Obviously, in all cases the result was due to decomposition, more or less pronounced, of the gelatine during drying. If there could be any doubt as to whether the decomposition had commenced before coating the plates it is set at rest by the fact, noticed by one of our informants, that a number of plates coated from the same bottle of emulsion gave perfect films a week or more after it had been used in the production of defective ones. In the case of the plates which refused to dry most probably the emulsion itself was also in fault, as in a similar experience of our own a few years ago we found the emulsion had not been properly washed, the films containing a considerable quantity of hygroscopic nitrates which, by delaying the drying, helped on the decomposition.

As to the cause of the decomposition, it is not far to seek. It lies in the drying-box itself. The practice of cramming a large number of plates into a small space to dry—a practice too common with amateurs—is one that results in more failures and troubles than perhaps any other. The idea that, so long as air space exists between the films, the box or cupboard may be crammed full, and that the same current of air which will dry a dozen will prove equally effective for a gross of plates, is one that cannot too quickly and completely be dismissed from the mind.

Putting the matter in its simplest form, the plates in drying give off their moisture gradually and regularly to the surrounding atmosphere. If this be stagnant—that is to say, if the space be confined and there is no ventilation—the atmosphere soon becomes saturated with moisture and drying ceases: hence the necessity for a constant change or current of air. Now, as air will only take up a given quantity of moisture (varying with circumstances) in a given time, it is plain that a current of air passing through a drying-box may suffice to carry off the moisture from (say) a dozen plates, while it will prove wholly inadequate for a gross, which number would require twelve times the volume of air or a current twelve times as rapid to effect their drying. With the larger number of plates and the insufficient current the atmosphere of the drying-box is constantly charged with moisture, the plates are unable to give off any more, or that but slowly, and the drying is checked.

We all know that gelatine in the presence of moisture (especially when the latter is accompanied by heat) rapidly decomposes; hence we need not be at all surprised if, under the circumstances noted above, plates dry unevenly. Of course a *hot* day in summer may vary very much in its character; it may be dry heat or it may be moisture-laden. It is the hot, close, heavy days, when the air is highly charged with aqueous vapour, which bring out the weaknesses of the drying-box. A hotter day if dry will probably cause little or no trouble; hence the reason of the result obtained with the weak, old emulsion quoted above.

The moral, then, is, if a drying-box *must* be used, not to overstock it; but it is far better, when possible, to dry in an open room well ventilated, as most of the commercial makers do. The ordinary coating-room will do if the window be covered with an opaque blind. The plates should never be left exposed to *any* light of whatever colour; and if the interval of night be selected for drying, no time will be lost. In any case the room should be left to itself, as any moving about would raise dust and spoil the films. At this season six or eight hours in an ordinarily-ventilated room will be found amply sufficient.

PRACTICAL DETAILS OF ALBUMENISING PAPER.

Resuming the above subject where we left it last week it will now be necessary to digress for a moment from the actual manipulations to say something about the drying-room and its fittings.

When the preparation of the paper is on a commercial scale the albumenising- and drying-rooms must be specially fitted up for the purpose. This is usually done by having light frames or racks constructed to hold the wooden rods over which the paper is laid when it is removed from the albumen. These rods are of deal and usually about the thickness of an ordinary broom handle. Rods suitable for the purpose may be purchased in lengths of from ten to fifteen feet at any of the steam moulding works, where they are rapidly produced by machinery, and are, therefore, very low in price. The wood should receive a coating of shellac varnish, and then be slightly polished with bees'-wax dissolved in turpentine—or, better still, rubbed over with a little cocoa butter. The object of this treatment is to prevent the edges of the paper adhering to the wood if, by accident, a trace of albumen should get on the back.

In close proximity to the dishes containing the albumen (which, by the way, must be placed in the coolest portion of the room) a frame should be fitted with holes, into which the ends of the rods will slip, the object being that when the paper is taken off the albumen it can conveniently be placed across a rod, fitted into one of them, where it is allowed to drain into a receptacle while the next two or three sheets are being floated, or until it ceases to drip. Then it, rod and all, can be transferred to the drying-racks. If the paper be laid across the rods diagonally—that is, with the two opposite corners lowermost—the albumen drains off more completely than if it were laid lengthwise or widthwise, as then we get an accumulation of albumen, forming a ridge, along the entire length of the two lowest edges; whereas, if the other plan be adopted, the albumen drains off from the corners of the sheet. It is true that this plan takes up a little more space; but that is more than compensated for by the advantage gained by being able to utilise the extreme edges of the paper without waste.

However, it is not our present purpose to discuss the preparation of paper on a commercial scale, as every manufacturer has his own particular method of procedure, our object being rather—as we said at the commencement—to show how the amateur, or professional with limited business, may prepare a paper to suit his requirements, assuming that such (as has been asserted) cannot be obtained in commerce. Therefore we shall now say a word or two on extemporising a room for the purpose. This is easily done by fixing a number of strings across the room, which, it is scarcely necessary to say, must be as free as possible from dust.

The room should be a dry one, and one that can be made tolerably warm, because it is essential that the paper should be dried off quickly after it is coated; otherwise a high gloss will not be secured. The requisite number of lines being fixed to contain the quantity of paper to be prepared, and a fire having been kept burning in the grate for a few hours previously, to warm and dry the atmosphere, we again turn our attention to the manipulation at the point we left off last week, namely, the removal of the paper from the albumen.

If the paper be lifted off quickly it will bring with it a large excess of albumen, which will have to drain away when the paper is hung up. If, on the contrary, it be gently and slowly raised it will take away but little excess—indeed, it is possible to remove the paper in such a manner that not more than two or three drops will drain off when it is suspended. This, however, is scarcely to be advised, as there may be a risk of not retaining sufficient on the paper. In practice the best plan is to take the paper by the two nearest corners, and gently "strip" it off with an even motion. On no account should a pause be made in removing the sheet, otherwise an uneven wave will be formed which will eventually dry in a ridge, and show in the finished print. The paper having been removed, it is then pinned by one corner to a line close to the coating dish—a vessel being placed below to catch the drippings—while other sheets are being floated. After the albumen has ceased to drip the paper is removed to another line in a warmer part of the room, where it is allowed to remain till dry. Instead of pinning the paper on to the line it might be laid across it, after the method employed with the wooden rods; but this is liable to produce a mark in the albumen by reason of the small diameter of the string causing a sharp fold in the paper.

We have assumed that the paper is being prepared in quarter sheets only; but if the whole sheet be dealt with it will have to be pinned up by two corners, as one will not be sufficiently strong to sustain its weight. Theoretically, paper suspended by one end, or by one corner, to drain and dry will not prove so evenly coated as if were hung from the middle; but in practice there is little difference and this little may be totally disregarded—certainly, in quarter sheets We may, in passing, mention that we know one very successful commercial albumeniser who for years used to, if he do not still suspend his paper from the end of the sheets. Whichever way the paper is suspended when it is taken from the albumen its direction must not be altered afterwards; otherwise the draining will be partially arrested, and an irregularity in the coating will result. When all the paper is coated the fire must be made up and kept burning, so as to ensure as rapid drying as possible. This is essential, or a highly-glazed surface will not be secured.

It sometimes happens—more particularly in hot weather—that innumerable minute bubbles will suddenly make their appearance on the surface of the albumen, and if they be skimmed off others immediately form. When this occurs it is useless to continue the work, as a decomposition or fermentation has set in. The inconvenience, however, is only temporary, and, if the albumen be put away in a cool place until the next day, it will be found to have recovered itself and be, apparently, in no way deteriorated Sometimes a few hours are all that is necessary for its recovery.

When the paper is dry professional albumenisers, as a rule, roll it with heavy pressure between metal plates, but there is really no advantage in this beyond giving it a smoother and more sightly appearance for the market. No difference whatever can be detected in the finished prints between those made on paper which has been rolled after albumenising and that which has not.

After the albumen has been used up so closely that no more paper can be floated, it is a good plan to collect what remains, together with that which has drained from the sheets, and to dilute it with an equal bulk of water containing seven and a-half grains of chloride of ammonium to the ounce—that is, supposing the albumen be salted in this proportion. Then a small quantity of paper should be floated on this, as a little lightly-albumenised paper is often very useful, particularly when extra deep purple or black tones are desired.

LANTERN ILLUMINATION.

The first thought that arises upon reading the report (in our last number) of the inquest upon the body of the man who was killed by the oxyhydrogen explosion in Drury-lane Theatre is surprise that, in a place of public entertainment like this, there could be such loose management in a highly-important department as to render such an explosion possible. We do not so much blame the individuals themselves—mostly uneducated for the purpose though they be—to whom is entrusted the working of gases in which lurk a large power for mischief, as the system under which such work is carried on. Perhaps it will be after the manager of some important theatre has fallen a victim to the inefficiency of the system and the incapacity of the *employés* to whose control are entrusted the preparations for, and exhibition of, the lime light that the managers of other places of public entertainment will bestir themselves in this matter, and adopt the necessary precautions for safety—precautions so simple and almost self-evident as to make "accidents" synonymous with results of carelessness.

That the employment of gas bags instead of gas bottles has much to do with such "accidents"—of which we read more frequently than we desire—there cannot be a doubt; nor is there any doubt that in the mixture, through carelessness or inadvertence, of the two gases (hydrogen and oxygen) in one bag lies the immediate origin of the explosion. Some exhibitors adopt the system of having one bag red and the other black, in addition to large initial letters, so as to prevent the possibility of a mistake; but we can readily enough understand that there are mental conditions which might for the time being so govern the manipulator as, aided by other circumstances, would even then cause him to mistake one bag for another. For this evil we see an effective remedy in the employment of compressed gas—the oxygen, in particular, to be employed in this condition.

The gas bottle or cylinder system, although recognised and in a small measure employed in England, exists in such a crude form as to be objectionable in no small degree. One objection occurred to us when examining such a bottle a few days ago. It was too small to contain an adequate supply of gas for an evening's entertainment of two hours' duration unless placed under a high degree of pressure; while to withstand such pressure the cylinder had to be formed of metal so thick as to make its portability one of some difficulty. In New York (as we learn from a communication received three years ago from our then American correspondent) the gas cylinders are sufficiently light to be easily handled, while at the same time they are not inconveniently large. A cylinder for containing fifteen feet of oxygen measures eight inches by thirty-two inches, and weighs thirty pounds. When fully charged the pressure is 225 lbs., but each cylinder is tested to 600 lbs. before leaving the factory where these receptacles are constructed.

An objection to the employment of an oxygen cylinder of the description referred to consists in the ever-varying pressure which, as it diminishes, necessitates more or less constant attention at the tap that regulates the exit. Again: there is such a lack of delicacy in the construction of the supply tap of the American cylinder as to necessitate the utmost care in regulating the flow of the gas. The lever must be moved with a very steady hand; for, if allowed to be carried only slightly too far, the oxygen rushes out with such velocity as to cause the reservoir to become quickly emptied.

Several years since, and in an editorial article in The British Journal of Photography (for December 7th, 1866), a tap was described which possesses every good quality that can be desired. Unlike at least one of more recent times with which we have had ample opportunity of becoming acquainted, the regulating milled-head moved quite easily without stiffness; and, similar to the fine adjustment of a microscope, it could be rotated to a considerable extent without *greatly* influencing the outflow of the gas. But, even with this, there still existed the objection consequent upon a constantly-diminishing pressure of the gas in the bottle.

To obviate this, various devices were at the time resorted to, the most feasible consisting of a small reservoir constructed like a bellows, under pressure, through which the oxygen passed from the reservoir, and by which it was supplied under a uniform pressure to the burner. When the supply in the bellows became nearly exhausted a lever attached to its wooden top operated upon the output tap of the reservoir by which the bellows received a fresh supply, the lever then cutting off any further output of the compressed oxygen. The smoothness of the outflow to the burner reminded one of the equable supply of air to the pipes from the wind chest of an organ.

We are pleased to learn that an easily-worked and practical automatic regulator of the outflow of gas from a compressed supply has been recently invented, and which, it is hoped, will soon be rendered available to everyone. Patents have been obtained for this automatic equaliser both in this country and in America, and in due course we shall publish full details, from which it will be seen that all objections at present existing against the employment of compressed gases have been anticipated. Let us hope that gas bags will soon become things of the past, and that convenient metallic receivers, and equally convenient force pumps capable of being employed by hand in the compression of the gas, will be available to all.

There is a class of lantern exhibitors for whose special requirements we would make a strong appeal. It is that class who, through being situated at a distance from towns or villages in which gas is laid on for illuminating purposes, must either make their own hydrogen or adopt some substitute for it. The ethoxo lime light, as we all well know, forms beyond doubt the most brilliant substitute for the mixed gases. Mr. W. Broughton, its practical introducer for this purpose, will be gratified to learn that within a brief period of his bringing the light before the notice of the Manchester Photographic Society it was so much appreciated in Philadelphia that a "cute" citizen of the United States had made application for a patent in connection therewith. Owing, however, to a recent explosion, an atmosphere of suspicion surrounds this convenient light just at present.

Too much praise cannot be accorded to the Rev. T. Frederick Hardwich for the strenuous efforts he has been, and still is, making to eliminate from the ethoxo light every element of danger. From such experimental researches of this honoured *savant* as we have published our readers will, with us, have arrived at the conclusion that there is a safe as well as brilliant future in store for the ethoxo light.

But there is a blow-through method which may be applied to ether as well as to carburetted hydrogen. We are unable at this moment to fix the date of its introduction, but in Griffin's *Chemical Recreations*—a work which, when published in 1846, became immensely popular with the rising generation of the period—there is a description, accompanied by a drawing, of an ether lamp, in the flame of which, if a piece of lime were held, it quite dazzled the eye. We append a brief description in order to show that so long ago as the date mentioned the heating powers of ether and oxygen were amply recognised, the lamp being of such a construction as to render any explosion quite out of the question.

A spirit lamp, containing ether, has a small wick formed of asbestos which, dipping into the ether, becomes saturated by capillary attraction in the usual way. It is encased in a burner-tube of metal or stoneware. Passing up through the centre of the wick is a small pipe, the upper end of which terminates in a blow-pipe orifice that is close to the surface of the asbestos wick, the lower end being connected with a bag of oxygen. "When the lamp is lighted and the pressure of oxygen set on, the flame becomes very small and gives little light; but it has such intense power as to be able to melt platinum instantaneously." This quotation is given from the original edition of the *Recreations*, and it demonstrates the impossibility of originating any of the conditions required for an explosion, while there is heat of sufficient intensity to provide a light that may be considered powerful enough for lantern exhibitions of the ordinary class.

Apropos of this subject, we would here (and still in the interests of those who have no gas near them) desire to put in a claim on behalf of a system of lime-lighting which, when managed at its best, is but little inferior to that obtained by the safety or blow-through jets—we mean the oxycalcium light. Its improvement has not kept pace with the times; yet we know that it is capable of giving a bright light on a sixteen-feet disc when all the conditions are favourable. But what these conditions are we had no opportunity of ascertaining from the exhibitor, who for one and a-half hour kept a screen of the above dimensions beautifully illuminated. The relation of the orifice of the blow-pipe to the alcohol wick, together with the hardness or softness of the limes, are the leading factors in determining the illumination. In our own experiments with this lamp we have obtained the best results when employing a low pressure, a large orifice in the jet, and a soft lime.

PERMANENCY, AND TONING AND FIXING.

A fortnight ago we dealt with the question of the connection between the permanency of prints and the chief material employed in their production—the albumenised paper. We now go a step further and discuss the materials employed, and the operations involved at a later stage of the process of printing, with a view of ascertaining to what extent they involve considerations of permanency. A consideration of the sensitising of the paper need occupy but little of our space in doing this, though of the fact of the salting of the paper and the strength of the bath affecting the degree of permanency of any print few will be inclined to entertain any doubt.

It is well agreed that makers at present put far less salt in the albumen with which they coat their paper than was the custom many years ago, and, in consequence, less strength is needed in the silver bath. It will, nevertheless, be conceded that as such weak solutions must lead to the production of a smaller quantity of precipitate within the coating of albumen upon the paper, and, as a consequence, an image composed of a smaller quantity of material than that produced upon a more highly-salted paper. It is evident that the greater the amount present of this image-forming silver salt the longer must be the time needed for the usual influences to set to work and give visible evidence of their action. A large portion of the image might be rendered colourless and yet leave sufficient behind to show up a vigorous image. With a thin deposit within the film, contrariwise, a very small amount of fading would show at once.

The first stage after printing is the preliminary washing before toning. Here there is nothing likely to occur that would tend to induce fading, for, except where the operations are performed in an unusually careless manner, any silver not extracted at this stage would be most probably got rid of during the toning and washing after toning. As, however, we know that a regard for ultimate permanence is not an active force with some workers, we may here point out that an ill-washed print quickly toned and immediately fixed would most probably contain a small quantity of silver—some of it possibly as nitrate; and, if it did, would as likely lead to a decomposition with the hypo.—a decomposition that might show at once or after a time.

Similar remarks may be made in regard to the toning, confining ourselves, of course, to "alkaline toning." It is next to impossible to perform this operation in any way that might induce a tendency to fugitiveness. One particular form of toning which has excited attention in its time has been supposed to tend to imperfect security; but it requires very little consideration to show that no foundation existed for impugning its integrity. We allude to the bath made of gold, neutralised with chalk, and chloride of calcium (not bleaching powder) then added.

This bath actually requires the silver to be imperfectly removed, the toning then being many times quicker than when the nitrate is entirely washed out; but it carries its own antidote in the action of the chloride, which would throw down the silver in a form very easily dissolved in the hypo. At the same time, if the print reached the hypo. too quickly, it would be possible for some trace of nitrate of silver to remain in the paper, and so lead to fading; for it will be understood that when nitrate of silver and hypo. are brought together a decomposition ensues which ends in the production of dark sulphide of silver, an infinitesimal proportion of which would suffice to injure the whites, so that, though the picture might not be said to "fade," it could not at anyrate be termed permanent.

It is at the next stage, however—the washing after toning—that danger is most likely to arise, and here, unfortunately, is disputed ground. Some first-rate printers hold that no washing here is needed, and that prints placed in the fixing, either direct from the toning or after the slightest of washings have been given to them, are quite as permanent as those which have received a plenteous washing, while being more beautiful to look at. This, it will be seen, is neither more nor less than a modification of the old combined toning and fixing bath freshly made, and it is difficult to see why if one is good the other should not be, and *vice versâ*. Our own opinion is strongly against this mixing of the two agents—the gold and the hypo.—even in a diluted form.

Actual experience may be able to throw some light upon this matter; but it must ever be remembered that an old unfaded print is not of great value as evidence unless a very completely-detailed record of all the processes and materials employed have been kept. The number of obscure and complicated reactions which occur in the use of so easily decomposable a substance as hypo. may lead to many errors being made if too much be assumed as to what existed, or did not exist, a number of years ago in the materials used in producing a given picture or set of pictures which have not faded. An extended series of pictures continuing over a considerable period of time would be very strong evidence of the best kind; but, failing any such data, theory must form a most important element in drawing conclusions as to the safety or otherwise of a given process.

With regard to the introduction of gold into the fixing: it has to be looked at from many points of view. The gold, or the hypo., may be acid or alkaline; a possible chemical change from the admixture may occur at once or require time for its development; reaction may set in between the two salts themselves or only when the hypo. has begun to dissolve the chloride out of the paper. These are a few of the many considerations that have to be dealt with in forming a judgment.

If anyone wish by experiment to see what will occur upon the admixture of gold and hypo. solutions he can very readily do so. He will find that neutral or alkaline solutions of gold cause upon the first admixture a decided change of colour, while acid solutions cause no such change, but yet cause the evolution of sulphurous acid, as indicated by a faint smell. Are such changes injurious or not? They have not been followed up theoretically, so far as we are aware; but it has long been shown that acid in the hypo. is injurious. Whether the change indicated by alteration of colour be so or not is open to investigation.

As a broad rule it may be stated that anything that causes a change in the hypo. solution should be looked upon with suspicion, and it would be safest to leave on one side any such chemical. How hypo. acts upon the print, and what its dangers are, form the most important part of our present survey. It is an old story, but may well be retold, if only for the benefit of those who have taken up photography since the days when this vital question was so well investigated. It is too wide and important a branch of this subject to deal with at the end of an article, and it is our purpose to conclude our *résumé* of matters germane to this part of the subject in a future number.

THE veteran Herbert Watkins is "on the war path" again, having been aroused by the capabilities of gelatine plates to a renewed enthusiasm for the profession from which he had some years ago retired. His attention will be chiefly engaged with instantaneous work, in which department he hopes to effect some great things.

IN portraiture it was, in former days, that Mr. Watkins made his reputation, and few photographers of the present time, even with all the increased rage for "celebrities," can, we imagine, show so valuable—so priceless—a collection of "portraits from the life" as one we looked over with our friend, Mr. Watkins, the other day, each picture being accompanied by a little story of the circumstances under which it was taken. Out of a collection of thirty or forty notabilities of the past generation we may mention, from memory, Macready, Lord Brougham, Lord Palmerston, Thackeray, Dickens, Harrison Ainsworth, Dumas Sen., Garibaldi, and Michael Balfe, with "Johnny" Toole, Sims Reeves, and Edmund Yates, in their "salad days," to keep up the connection with the present generation. Each of these pictures dates back at least twenty years, many of them far more, so that we may soon begin to believe that photography is growing out of its infancy.

THE portrait of Henry, Lord Brougham mentioned above is the only photograph of the deceased statesman we have ever seen. We wonder if it be the only one in existence. If so, the personality of a character whose name will figure so prominently in future history should be preserved for posterity, possessing as it does that impress of truth which only photography can give. The early pages of *Punch* supply innumerable representations of the remarkable features of one of the leading politicians of that day; but, however good as caricatures, these will never pass to a future age as portraits.

THE question of colour value, colour sensation, &c., is surrounded with difficulties of which those that may be termed the "mechanical" are not less than others connected with the personal equation of the observer, some interesting examples of which latter quality were exemplified at a recent meeting of the Photographic Society of Great Britain. When an observer is colour blind to a considerable extent—in all probability without knowing it—his verdict as to the power of a certain light in a dark-room window is not likely to coincide with that of another possessing a natural power of distinguishing colour. And when it is desired to note and compare the effect of the admixture of colours most instrumental means are really inadequate, and the better class are cumbrous or costly. Thus many of Helmholtz's recorded experiments were founded upon the admixture of lights from coloured discs, which evidently left unexplored a very wide field. A communication, however, was recently read before the Physical Society, describing a new form of instrument, which would seem to offer considerable facilities for investigating these phenemona so interesting to the photographer. The colours are obtained by sending the light from a series of incandescent wires through prisms, and the instrument enables those different rays to be superposed at one time. If this should prove to be a serviceable piece of apparatus it may be expected to shed considerable light upon the subject.

We mentioned a few weeks ago a sample of sheet gelatine which exhibited a remarkable form of dichroism, the colours shown being green and red respectively, according to the number of thicknesses of material. We have since been shown a piece of coloured gelatine which exhibited in a very remarkable manner the transparency of coloured media to other than the prevailing tint. This particular piece of gelatine appeared of a bright, bluish-purple hue, and when held in the hand seemed to impart that tint to all objects; but when brought close to the eye, and a face viewed through it, the predominant colour given to it was not purple but crimson—a result so unexpected as to be almost startling. A more instructive experiment could not be given to show, in a popular manner, how incapable the eye is of forming a true opinion of the transparency of a medium to any particular coloured light.

Still on the subject of colour: a correspondent writes to us, *apropos* of Mr. Sawyer's letter, that last year he used a window coated with aurine dissolved in ordinary spirit varnish for the purpose of screening his silvered paper, and so is in a position to give an account of its value. The window faced due east, and for a while appeared to hold its own against the light; but after a month or two it rapidly changed and became quite useless.

A dark room for scientific purposes eight feet wide may be ample, but is certainly not remarkable. When, however, we read of the walls of such a room being six feet thick there is occasion for some surprise. These are the dimensions of the photographic dark room which is to be added to the Ben Nevis Observatory, an account of the opening of which we gave to our readers last October. The station has been so successful that great results are expected from it in the future, and it has been determined to double its present size, with the result of the accommodation just named for photographic purposes being designed.

The pursuit of astronomical photography presents many difficulties of no light nature in the path of its votaries. No one, for example, would consider the necessary watching in the small hours for favourable opportunities to secure stellar or lunar photographs as a light pastime for leisure hours; still less would he look upon an observer lying on his back on a cold winter night for an hour and a-half steadily turning a handle as engaged in frivolous amusement, even though the observer were a clergyman. These troubles, however, are trivial in connection with one that recently the Rev. T. E. Espin had a narrow escape from. Engaged in near proximity to the rear of his church, with his scientific paraphernalia about him, ready to seize a suitable moment for his favourite work, he was alarmed by a sudden flash of light, which he knew came from neither comet nor meteor, and to his horror he was seized from behind by two stalwart men. Their bull's-eye lantern revealed them to be policemen, and they arrested him as a dynamitard! Fortunately a catastrophe was averted, for the men discovered they had arrested their pastor, and their dismay may be more readily imagined than described.

At a meeting of the Royal Astronomical Society, on the 13th inst., Mr. Ranyard read an original paper on *The Cause of the Blurred Patches in Instantaneous Photographs of the Sun*, in which he gave a most ingenious explanation of the possible mode by which the phenomenon might be produced. M. Janssen explains these appearances in his own photographs as being due to solar clouds or gaseous masses above the photosphere, which he supposes to change rapidly; but Mr. Ranyard attributes them to currents of heated air within the body of the telescope. He placed a heated iron chisel in various positions in his telescope tube, and by the effects produced upon the image of a star out of focus he was able distinctly to localise the spot where the hot body lay. Following these indications he took an instantaneous photograph of the sun with the hot iron near the mouth of the telescope, and also one when the sun was just seen above a heated roof. In both cases the limb of the sun was much distorted, and brighter areas were seen extending into the disc of the sun.

There seemed a tendency to banter the reader of the paper, Mr. Common's remark that "with perseverance no doubt very bad photographs can be got, but the important question is how to get good ones," being received with laughter. It was, however, scarcely a fair remark to make, and the explanation offered by Mr. Ranyard appears a very natural one. Plenty of food for thought, and work for committeemen, may be got out of the sun's legitimate appearances without inventing solar facts to account for mechanical or instrumental vagaries.

LIME-LIGHT EXPLOSIONS AND THEIR PREVENTION.

There seems no doubt whatever that the safety tubes on which I have been lately experimenting are quite effective in preventing lime-light explosions, and it is to be hoped that they will be much used during the coming winter. I foresee, however, that the result will not be entirely satisfactory unless certain little points are attended to. The opticians who manufacture these tubes must supply with them an extra quantity of the granulated pumice or tin filings, as the case may be, to be kept in stock; and also little circular discs of wire gauze, cut out with a steel punch and slightly larger than the tube, so that they will not move when pushed in on the top of the filings to keep them in position.

Those who wish to make their own safety chambers can easily do so by cutting a piece of tin or brass tubing about three-quarters of an inch long by half-an-inch wide, and filling it with slate siftings. A disc of wire gauze, sixty meshes to the inch, must be placed at each end as before described, and the tube may then be attached to the jet by a connector of vulcanised rubber. To prepare the siftings crush two or three slate pencils in a Wedgwood mortar, and throw the coarse powder on a sieve of thirty-six meshes to the inch. All that passes through must be screened from dust by a second sieve of sixty meshes to the inch, and the rough pieces left on the first sieve returned to the mortar for further pulverisation. In this simple way a material is produced equal to the pumice as far as I have tried it, and sufficiently free from dust if well screened.

I find that after the tubes have been long used the wire gauze is apt to become rusted and choked up, so that from ten to fifteen per cent. is taken off the pressure of the gas, independently of the granules. The lecturer should accustom himself to examine the tubes beforehand by drawing air through them with the breath, and should put in fresh gauze whenever it is required. This can be done in a few minutes if the tubes be made to open at both ends; and they can be rendered gas-tight by a small washer of lead, or, better still, by springing a piece of vulcanised rubber over the whole length of the tube flush with the milled heads of the caps at the ends. If the red rubber be used it will present a very neat appearance, and when once the rubber is on it will not be necessary to remove it in unscrewing the caps. Tested by suction the tube will be found to be quite air-tight if the screw has been greased with a little tallow.

The credit of this invention belongs to Mr. Broughton, of Manchester; but I presume he will place no restriction upon the manufacture of the tubes, since we are all interested in restoring the confidence of the public, and in enabling them to listen to the instruction we have to impart, without any nervous fear of an explosion.

T. Frederick Hardwich.

AN ELECTRIC TIME ALARM WITH AUTOMATIC SHUTTER.

Those who have much to do with copying and enlarging cameras, in which the exposures are usually not timed in seconds, feel the desirability of some kind of alarm to warn them of the termination of those periods, and a shutter to cover up the lens at the same moment the aural notice is given. It is not always convenient, when two or more cameras are employed, to attend to any one of them at the proper time, either in consequence of being engaged in the dark room or lest others should be shaken by moving about the floor; besides, one's memory does not always serve. Time appears to pass so rapidly the more busily an operator makes use of it that the interval is found to have been exceeded on referring to the clock, the result being a spoiled plate; whereas, if each of the instruments were fitted with a shutter and bell in electrical communication, and controlled by the timepiece, failures from such a cause would cease to be. To this end I intend to describe a moderately simple and cheap arrangement for the purpose, and, by way of preliminary, to indicate the requirements and give some idea of the conditions whereby electrical energy may be applied to enable photographers, who are not even amateur electricians, to fit up the thing for themselves.

The mechanical and other appliances consist of a cheap American clock (preferably one of the older forms in wooden case), a charged No. 2 Leclanché battery, a small electric bell, and an electro-magnet for each camera fitted. A few yards of silk or cotton-covered copper wire, and some small terminals for convenience in connecting up, completes the list. These may all be purchased at a cheap rate, and are permanent, with the exception of the battery, and this might also be considered so, in that the slight amount of work it has to perform will not necessitate its being re-charged more than once a year, and only costs a few pence if sent to an electrician to be done. This form of battery is so common an article of commerce that it scarcely needs description here; as it is, however, the source of power, a little must be said respecting its action.

Upon the top of the jar are two terminals, soldered respectively to a plate of carbon and a rod of zinc. These are called the poles, and, while unconnected by a conductor of electricity—which, to speak roughly, consist of metals and non-conductors of wax, dried wood, glass, ebonite, gutta-percha, resinous substances, and so forth—no action takes place among the chemicals and metals in the receptacle; but when connected a re-arrangement of the elements of these substances takes place, and developes the subtle and peculiar energy known as electricity which flows through the conductor. This course of the current is called the "circuit," and will in our case be of copper wire, in which the apparatus for utilising the energy will be placed and form part of it. A covering of cotton or silk is advisable to prevent leakage or short-circuiting through some material affording a path of less resistance between the poles of the battery than that of bells and wire.

As it is not intended to allow the energy to waste by continuous action of the battery, but to make it available at the right moment to perform the service required, the line is severed and connected up to the clock in such a manner that the making and breaking of the circuit is controlled by its agency alone. More on this point further on. To convert the current into the servant: the quality it possesses of magnetising a piece of soft iron placed in a helix of covered copper wire through which it is passing, and therefore conferring on the soft iron core, while under its influence, the property of attracting that metal, is the only one to be here noticed. The electric bell and shutter being both actuated by one of these electro-magnets, and the whole being purchasable ready to connect up in the wire, nothing further need be said respecting their construction.

To prepare the clock for its office: provide it with a base piece if to stand, or a backing if to hang, of thoroughly dry wood, and secure upon the dial in the track of the end of the minute hand a little flat staple of wire partially embedded in ebonite or gutta-percha, to insulate it from the metal of the dial and other portions of the clock—one of the ends of the wire to run through the substance of the insulator to a terminal also set in it. The timepiece thus becomes a contact-breaker when placed in circuit—by connecting the wire from one pole of the battery to the terminal of the contact on the dial, and that from the other pole to the metal framing of the clock work—and only permits a passage of current insulated upon the dial whilst its minute hand is travelling over and touching the wire staple.

The electric bell and electro-magnet for the shutter we will pass over, in supposing them to have been bought and all right for fitting up.

The shutter for the lens is of the simplest character. It is composed of a piece of three-quarter inch deal, in length about three times the diameter of the hood of the lens, and in width about twice the same. At the lower end a hole is cut to fit on the hood, and on its face, a little more than the width of the aperture, are glued some strips of wood for the shutter to slide in. This need be but a little longer than the aperture in the board, and when raised for exposure is held in position by a small iron bolt which is drawn to release it by a small electro-magnet fastened on one side of the board.

Having provided the mechanism — battery, clock, bell, and shutter—the fitting up is the next consideration. In the first place, connect up one pole of the battery, by means of covered wire, with the works of the clock. The union thus effected may be looked upon as permanent, because, whether the clock be used to regulate one or many cameras, it serves for all. From the contact on the dial a piece of wire is taken to one terminal of the bell, another length connects the other terminal with one of the electro-magnets on the shutter, and, finally, another length unites the second terminal of this last with the other and vacant pole of the battery. It will be then found, as stated above, that the circuit is only complete when the hand of the clock touches the metallic contact on its dial, the action of the contrivance being as follows:—When an exposure is to be timed—say, for five minutes—the hand is set back that interval from this contact, and the shutter drawn and bolted. At its expiration the hand makes contact, and, completing the circuit, the electric energy magnetises the soft iron cores in the electro-magnets of the bell and shutter, enabling them to attract iron in their vicinity and perform the duty required—to give an alarm and release the shutter, which falls by its own weight and terminates the exposure.

Should the clock be required to regulate the exposing contrivances of several cameras, or do other work of timing either separately or simultaneously, there is no difficulty in fitting it for the duty. For one instrument at a time only the one contact on the dial is needed. This on being connected up by wire to a board to which the wires from the various apparatus are brought, the current is carried through any one of the series by uniting it with the clock wire by means of a switch—a strip of spring brass screwed on the one wire and capable of being turned to touch any of the others.

For simultaneous regulation a slight modification of the clock will be necessary. As each set will require a hand and contact on the face, there must be an extension of the hand arbor of the clock to admit of several being placed upon it. The hands, instead of being put on a square, must be slid upon the round spindle and fit sufficiently tight to move with it; but not enough to prevent the setting back of any one of them upon it. A key or cross-piece on the end of the arbor will be very desirable for checking any tendency to its turning with the hands. The contacts must be in steps, as it were, rising outwards, and the hands respectively of suitable length for each one. If half-a-dozen or fewer be used they must be placed on the spindle in the order of their size, the shortest one first—each one, in setting, to be put back from the contact to which it has been paired. In employing several bells they should be chosen differing in tone as much as possible, to avoid confusion.

An electrical servant of the above description can be usefully employed in many other ways besides timing exposure — in fact for any purpose where the period is definite and known beforehand.

JOHN HARMER.

PHOTOGRAPHIC INDUSTRIES.

THE SCIOPTICON COMPANY.

DESIROUS of becoming acquainted with the state of the sciopticon as regards the probable demand for it during the forthcoming season (for the lantern trade of the winter makes itself felt among manufacturers several months in advance), we took occasion to pay a visit to the head-quarters of the Sciopticon Company at 26, Colebrooke-row, Islington, London, in which place it is established under the management of Mr. George Smith—a gentleman well known to our readers as an able writer on many topics, especially those cognate to applied optics and projection.

But Mr. Smith does not confine himself to "scioptics" alone, for he has also entered the domain of photographic apparatus construction, confining himself in this respect to what are mainly his own inventions. At the time of our visit Mr. Smith was contemplating, with the fond eyes of a parent, his latest achievement in the way of camera stands—the "Manx stand"—so called, as he explained, as being an embodiment of the sentiment conveyed in the Manx motto, *Quocunque jeceris stabit.* This, the latest-born among portable stands, partakes in some of its features of the Kennett stand, only being much lighter, while the lightness is not secured at the expense of rigidity. Without a drawing it is very difficult to convey a precise idea of its various details; but we may say that in the sliding central portion of the leg, by which the height is adjusted to suit the requirements of uneven ground or elevation of point of sight, rigidity is conferred upon it by a clever adaptation of the T system. There are many neatly-contrived adjustments connected with the Manx stand, indicating thoughtful care throughout in its construction.

Conversing on the subject of the size of camera possessing the balance of advantages for the amateur tourist photographer, Mr. Smith gave it as his opinion that the quarter-plate camera fulfilled this requirement in a manner more perfectly, perhaps, than any other. In proof of this he showed us his own working outfit neatly packed in a leather case. It comprised a camera of the dimensions just mentioned, having a focussing-range extending from two to twelve inches; a small battery of lenses, also part of the outfit, providing the means of obtaining photographs at either extremity of this great focal range, or anywhere throughout its scope. A supply of eight plates for the single journey is contained in four double dark slides. The quarter-plate size, Mr. Smith states, is all that is necessary when one desires to print from the negative direct on to lantern-size plates for transparencies of $3\frac{1}{4} \times 3\frac{1}{4}$—the recognised standard dimensions of pictures of this class; while, if larger prints are desired, the negative is sufficiently sharp to produce them, by a simple system of enlarging, up to 15×12 inches.

Respecting the capabilities of single achromatic lenses for portraiture, we were shown by Mr. Smith some portraits obtained with single lenses the working aperture of which had been enlarged to $\frac{f}{6}$. While amply sharp enough in the face the definition of the parts of the figure remote from the face was of a pleasing degree of softness, contrasting favourably in this respect with the definition obtained with a portrait lens having a large angular aperture, by which some portions were extremely crisp and sharp, while others contiguous, but situated on another plane, were quite hazy and indistinct. The property inherent in single lenses by which this great contrast can be obviated has frequently been brought before our readers.

There is a material known as "vulcanised fibre" that has recently been introduced, and likely to prove of great value in various departments of photography, which we saw commercially utilised for the first time during our visit. This material is up to the present time supplied only in sheets, these being of various degrees of thickness. It is said to be prepared with parchmentised paper; at anyrate, it is light, impermeable to the action of acids or alkalies, quite flexible, and exceedingly tough. Mr. Smith has been trying the effect of employing this substance instead of brass for making lens diaphragms, and there can be no doubt of its value for this purpose.

He still adheres to the system, introduced by himself, of providing for a long focal range in the camera by a duplex system of tailboards—one made in three pieces, and wrapping round the camera when closed, like the cover of a book. When these are opened out and kept in a distended and rigid position by suitable fasteners, the body of the camera can travel from end to end of this double or triple tailboard.

The basement of the sciopticon premises is devoted to the production of moulds and the printing of lantern slides by the Woodbury process. Here stands a powerful hydraulic press, by which the gelatine reliefs are pressed into the surface of the lead printing moulds. Of these latter we saw several hundreds stacked away on shelves, all being classified according to the subjects. A distinguishing feature of lantern slides made in this manner is the transparency of even the darkest shadows, while the tone is entirely at the option of the printer, who can employ ink of any colour according to the inclination of his mind. That which Mr. Smith has adopted as a standard colour is a peculiar sort of dark brown, which he finds meets with more general acceptance than any other. It is of a tone much like that which characterised the transparencies of the now extinct firm of Ferrier and Soulier, of Paris.

There are also several printing-presses here of simple form, but which have been found well adapted for transparency printing. In this class of work it is absolutely indispensable that thin plate-glass be employed. This department of photography, we may here observe, is one with which Mr. Smith is exceedingly familiar, having been at the outset a pupil and an assistant of Mr. W. B. Woodbury's, and having for several years subsequently occupied an important technical position in the Woodburytype department of Goupil and Co., Paris. The supply of lantern slides kept ready in stock is both great and varied. Mr. Smith is a strong believer in the efficacy of the double-wick sciopticon in contrast with those in which the light is obtained from three, four, and even five wicks, and considers that the slight increase of illumination is dearly purchased by the greatly-increased heat.

We were shown a new adapting slide-holder for the lantern by which the effects of dissolving views could be obtained when employing a single lantern only. As this slide-holder possesses some features which we think exceptionally valuable, we shall defer the details connected with it till a future number, more especially as it could scarcely be said to be in quite a completed form at the period of our visit. Still we may here state what effect is produced. The picture is seen fully illuminated upon the screen, the source of illumination being either lime or petroleum; a diminution of the light then takes place, more or less rapidly at the option of the exhibitor, until it culminates in an instant of darkness, after which the light again increases to full intensity, but with a *different* picture now on the screen. The rapidity with which one plate may thus be merged into another is entirely under the control of the exhibitor, who can either prolong the transformation during a quarter of a minute or flash it off in half-a-second. The means by which this is effected will form the subject of another article in an early number.

The upper portion of the premises is devoted to the brass work connected with a growing manufacturing business, in which metallic fittings play no insignificant part. Mr. Smith, we may observe, is quite at home at the work-bench and turning-lathe; and in this respect, and unlike many other inventors, he possesses the advantage of being enabled to carry his special ideas into practical effect with his own hands.

EXPERIMENTS WITH PHOSPHITES AND VARIOUS ACIDS IN DEVELOPERS.

The objection to sulphite of soda in the developer, raised in these pages some time ago—that it acts as a restrainer—was experimentally refuted by the Editors, who proved that it, by itself, acts as a slow developer, which was to be expected, because all developers, including pure sulphite of soda, are absorbents of oxygen. Another reason is that it has a feebly-alkaline reaction, and the presence of alkalies increases the absorption of oxygen by silver reducers. Then, again: sulphurous acid is one of the weakest of the inorganic acids. It is not much more powerful in its combinations than carbonic acid; so that there are certain resemblances between carbonate of soda and sulphite of soda—the former, however, having the stronger alkaline reaction. As sulphite of soda is a developer, how is it that a solution of it rendered slightly acid preserves pyrogallic acid? This may be because there is so very much matter in the concentrated solution to oxidise, and because the specific gravity of the liquid is such that when its upper surface is oxidised the thin film acts partially as a protecting layer upon the bulk of the liquid below. Without the sulphite the oxidised layer sinks in streams to the bottom of the solution, fresh liquid takes its place, to be in turn oxidised, and so the whole mass discolours rapidly. The oxidised solution is a brownish-yellow vegetable dye.

Undoubtedly sulphite of soda slows development, which is a different thing from slowing the plate. To operators not in a hurry from commercial stress or other reasons, the lengthening of the time of development by a minute or two is an advantage rather than otherwise. The whole operation is then more under control, and it is easier to hit the proper intensity, thereby avoiding subsequent strengthening or reducing of the negative.

Wishing to know the function of acids in the sulphite of soda developer, and to what extent different acids affect the colour of the image, I tried several new developers, all of which worked well. The first picture was, however, developed with the usual sulpho-pyrogallol developer, slightly acidified with citric acid in order to compare it with the others. The acidulated sulpho-pyrogallol and bromide of potassium were applied first to the film that it might obtain the benefit of the action of the free acid before the latter was neutralised by ammonia. By soaking the plate in this way for more than a minute, and brushing its surface under the liquid before the addition of the ammonia, it is easier to obtain clean, unspotted, and dense negatives. Soaking the plate with water alone before development has always had a bad effect in my experience.

The following are the new developers tried. The sulphite of soda used was the recrystallised variety; all the chemicals employed were those of Messrs. Hopkin and Williams, except the pyrogallol, which was Schering's. In all cases, of course, the acid was put in the liquid before the pyrogallol was added.

1. Lactic Acid.

The stock solution consisted of—

Lactic acid	60 minims.
Saturated solution of sulphite of soda	1 ounce.
Pyrogallol	45 grains.

In this and all the succeeding experiments, before developing, one part of the stock solution was added to fifteen of water containing the bromide, and the ammonia was added after the plate had been treated in the manner already stated. The above stock solution at once took a faint, pinkish straw colour.

2. Bisulphite of Soda.

The stock solution consisted of—

Saturated solution of bisulphite of soda	1 ounce.
Pyrogallol	45 grains.

This salt is strongly acid to test paper; in fact, it will dissolve zinc, and undergo decomposition in the process. The solution was of a feebly-tinted, blackish-green colour. Bisulphite of soda is much less soluble in water than the sulphite.

3. Sulphurous Acid and Sulphite of Potash.

Water	1 ounce.
Sulphite of potash	2 drachms.
Sulphurous acid	1 drachm.
Pyrogallol	45 grains.

The sulphite of potash had an alkaline reaction, and the above quantity of sulphurous acid made it but slightly acid. The solution was of a dark, sage-green colour.

4. Carbolic Acid.

Saturated solution of carbolic acid in water	1 drachm.
Water	7 drachms.
Pyrogallol	45 grains.

At the time of mixing, this solution was colourless; but it gradually took on a yellowish-brown tint, and at the end of three weeks became the colour of ordinary negative varnish. Carbolic acid or, more properly speaking, phenol, is not an acid at all; the behaviour of this developer was, therefore, unlike the others, as stated farther on.

5. Phosphorus Acid.

Water	1 ounce.
Phosphite of potash	110 grains.
Pyrogallol	45 ,,

The phosphite of potash had an acid reaction of its own. The solution was a dark, sage-green colour, and slightly opalescent before and after filtering. In three weeks it exhibited symptoms of slight turbidity, but was possibly only ridding itself of that which caused the opalescence.

6. Phosphorus and Citric Acids.

Water	7 drachms.
Phosphite of soda	220 grains.
Solution of one drachm of citric acid in eight drachms of water	120 minims.
Pyrogallol	45 grains.

The phosphite of soda had an acid reaction; but on adding the pyrogallol it went a dark colour, so I added the above citric acid, which at once partially decolourised it. I do not now think that the addition of the citric acid was necessary; for the dark colours struck with the phosphite salts appear to be harmless, and do not show in the developer when first diluted for use. The stock developer now under notice assumed a greenish-brown colour.

The general result of the trial of all these developers was to show that, with ordinary exposures, the particular acid in the developer has very little influence on the colour of the image, though it has much on the colour of the developer. The free acids in these developers all acted as restrainers, with the development conducted in the manner already stated. In fact, with the very acid, bisulphite of soda, No. 2 developer, more than treble the usual exposure of the plate was necessary. On the other hand, as the exposures were lengthened and the developers made more acid the vigour of the images increased, and acquired more the characteristics of those taken on chloride of silver gelatine plates. I am not sure whether by following out these principles it may not be possible to get the same class of transparencies as with chloride plates, and to avoid the long exposures to lamp-light on the one hand, or to burning magnesium on the other, as well as to avoid keeping one set of plates for transparency printing and another description of plates for the camera.

According to Miller, sulphite of potash in solution undergoes slow decomposition in closed bottles; and a recent paragraph in these pages announced that a French chemist had stated that sulphite of soda in solution slowly decomposes. The latter paragraph may have merely meant the ordinary decomposition by oxidation; but if it meant decomposition in closed bottles the subject should receive attention. Watts says that the solutions of the phosphites alter little by exposure to air, so there is a probability of advantage in substituting them for the sulphites in developers.

These experiments proved to me that variations in the amount of free acid in the sulphite class of developers affect the results—whether more so by my method of applying the developer than by other methods I cannot say; but, as the citrates of the alkalies are powerful retarding agents, it is probable there is restraining in every case. A bad sample of sulphite of soda is a mischievous thing, because the decomposition of any free carbonate of soda in it, when citric acid is added, produces the strong restrainer, citrate of soda, in the solution; therefore the sulphite of soda should be pure and recrystallised.

In all cases litmus paper should be called into use when mixing the sulphite developer. When the solution is but just neutralised, or but faintly acid, it has much more tendency to fog the plates than if a little more acid be added. The stock developer may give a fairly-strong reddening of litmus paper before the acid is in sufficient ascendancy to effect retardation of practical importance; but the chances of fog are greatly diminished. Some of the discrepant experiences of various new users of the sulphite of soda developer may have been due to their following one formula, and mixing the same quantity of citric acid with different samples of sulphite of soda. The latter must be pure to be sure of good results, and the mixing should be done with the aid of the information given by test papers.

As an example of the danger of using different samples of sulphite of soda indiscriminately, it may be mentioned that while at Lucerne I received a French sample of the salt, and did not recognise it, its appearance was so "chalky." Seven ounces of saturated solution of it were made and filtered, and having no litmus paper at my hotel I took the solution to Herr Brunck, of Zuricherstrasse, to be rendered very slightly acid before adding the pyrogallol. He informed me of a more delicate test than litmus paper, namely, a very weak solution of cyanine, the beautiful blue colour of which is destroyed by the feeblest trace of acid in any liquid added to it. To hit this neutral point we had to put into the seven ounces of solution at least a quarter of an ounce of strong sulphuric acid, that acid being selected for the purpose of liberating a little free sulphurous acid. The quantity of carbonate of soda in the original sample of "sulphite" may therefore be imagined, and had the neutralisation been performed with citric acid a heavy amount of the powerful restrainer, citrate of soda, would have been in the developer. This abundantly shows the necessity for using test papers or test solutions, and pure chemicals, in making the sulphite of soda developer. This developer works best when not quite neutral; it should have a moderately-strong acid reaction. I did not find that sulphate of soda acted very strongly as a restrainer, much of it as the solution contained. Many salts, containing more oxygen than the sulphites, act as restrainers in chemical actions. An article by Mr. Hood in a back number of the *Philosophical Magazine* states that the oxidation of ferrous sulphate through chlorate of potash is retarded by the presence of the sulphates of potash, soda, ammonia, and other salts, in proportion to the weight of each inactive salt added. In photography any tendency to yield oxygen checks development, and any tendency to absorb oxygen increases the energy of development; even salts chemically inactive seem to exercise some little "strain" in either the one or the other direction.

On my notes are the following items of further information about the six developers already mentioned:—

The lactic acid developer, No. 1, gave a bright image, which came out rapidly. This acid possesses much power in the way of preventing the decolourising to any great extent of the pyrogallol stock solution, which in three weeks has undergone no visible change. The lactic acid used was not very strong, but that known as "medicinal," specific gravity 1040.

Developer No. 2, with bisulphite of soda, was so acid that it required about three times as much ammonia as the other developers to energise it. I find the curious remark on my notes that the plate developed with it took longer than the others to fix in the thiosulphate of soda solution, but this requires verification by more experience.

The sulphite of potash developer, No. 3, presented no unusual features. The carbolic acid developer, No. 4, darkened rapidly over the plate; in short, it behaved just like the ordinary pyrogallol developer without sulphite, and the image came out quickly. No. 5, with phosphite of potash, gave a vigorous image; the diluted developer became slightly opalescent. No. 6, with phosphite of soda and much citric acid, gave one of the best transparencies of the series; but the exposure was necessarily longer than with plates for development in a less acid solution. The developer acquired a deep colour—not irregularly; yet I do not think it was more decomposed than if the ordinary sulphite developer had been used. These colours of the liquids are very deceptive, and, as a rule, are harmless, forming no guide as to the relative amount of decomposition going on in various developers. The phosphite of soda developer took the colour of strong old ale over the plate.

All these stock solutions work well; and, as I use them up, if they should present any peculiarities not yet observed, any such points of interest will be published. W. H. Harrison.

ON THINGS IN GENERAL.

Oxygen explosions still to the fore! I suppose, also, they will be till the arrival of the millenium. The first time a man starts exhibiting lime-light, if he be not thoroughly ignorant, he is generally in a state of nervous tremor; and when he makes oxygen, if he have heard anything about its danger—a problematical occurrence, by-the-bye—he almost buys a suit of plate armour against possible explosions. But after a few trials, when he finds the whole thing so simple, he rapidly proves the truth of the adage, "Too much familiarity breeds contempt," and he has nothing but wonder for the fools who have "blow-ups," till, perhaps, some day he finds himself testing the strength of the ceiling with his head. When, however, the work is delegated to ignorant servants, the occasional occurrence of accident is an actual necessity, and the wonder is that there are not more of them. Even if the danger be well known to them, and steps devised to prevent accident, they will not make use of them. There are manufacturers who will not have their steam-boilers examined by an official examiner as they might be put to expense in repairing them; and there are workmen who load the safety-valve. The same class of treatment is given to gas bags, and would be to nitro-glycerine if it could be turned on by a tap. One has only to observe the usual course of proceeding when there is an escape of gas. Most people know that if it get alight it will explode, so the common plan is to strike a light at once and apply it where the gas smells strongest, with the idea, I presume, of ascertaining whether it is dangerous. Unfortunately, too many of these rash persons carry the knowledge to the grave. I do not for a moment wish it to be supposed that I would deprecate any attempt to introduce safeguards; the more, and the better in quality they are, the fewer the accidents there will be. But it is useless for anyone to expect perfect immunity from accident when the ordinary plan of the workman, who imagines that the gas has got mixed, is to apply a light to the tap to ascertain the fact. The minstrels who were performing at Drury-lane where the accident recently took place deserve a medal for their presence of mind, for it prevented the occurrence of a panic. As soon as the noise showed something to be wrong they interpolated a few comic remarks, and led the audience to believe that it formed part of the entertainment.

Explosive substances seem to connect themselves most closely with photography. With ether, pyroxyline, oxyhydrogen, &c., so constantly in use, no wonder the fire insurance companies make us pay heavily; and now we have still more dangerous chemicals suggested. M. Guyard has proposed iodide of nitrogen as a light measurer—a chemical which will literally explode by a breath of wind, and cannot be kept in quantities of more than a few grains at a time. I note a correspondent of this Journal writes to the Editors to know if iodine dissolved in ammonia would remove very bad silver stains. He is informed that they will, but is cautioned to keep iodine always in excess to avoid the formation of the above-named terrible compound. But why use such a compound at all? A preliminary treatment with strong solution of iodine, followed by cyanide or even hypo., is quicker than any plan known. It is incontestably superior in point of efficacy to any other plan published; but it has not been told more than a thousand times, so I presume it is not generally known.

Mr. W. Coles's paper on *Altering the Density of Gelatine Negatives* was a most useful one, though, as a matter of course, he could not include all good methods. He must be a courageous man, for he positively admitted that it was possible for him to make an error of judgment in the density of a negative. My experience of photographers is that, like doctors and lawyers, they never make a mistake. Mr. Coles no doubt believes with me the philosophical dictum—"Show me a man who never made a mistake and I will show you a fool."

Mr. E. Dunmore, at the last meeting of the Parent Society, made a very pertinent remark *anent* permanency. He said the word "might have a very elastic meaning; it might be used as meaning indestructibility or durability." I can give him an instance showing that the public may put the former construction upon the word. A reception-room attendant was showing to a lady a beautiful picture in water colour upon a carbon print which had just left the artist's hands and was not yet framed. "This is done by the permanent process." "Is it," was the reply, and the lady quickly rubbed the face of the picture with her gloved finger before she could be interfered with. *Tableau!*

I see that Mr. H. B. Berkeley has been complaining about the reports in the journals of the meetings of the Photographic Society of Great Britain. He says:—"Under the present system of publication of a non-official character such errors must remain inevitable." Mr. Berkeley is nothing if not logical. Where is the logic here? By the same argument all the summaries that appear in the daily papers even are necessarily inaccurate!

I was much interested in reading the account of the method of getting rid of obtrusive backgrounds that the editor of the *Photographic Times* (New York) devised. He made bonfires, and the smoke formed a screen that quite obscured the objectionable parts. Our old friend is a lucky man, or deserves to be; but was not the wind a very convenient wind on the occasions he named—never once blowing the smoke the wrong way, on to the foreground instead of off it!

Photography and fine art are again in collision on the continent. This time there is actually on view a photograph and a painting of the same spot—the interior of a studio—with similar surroundings, and the painter is accused of undue use of the photograph. The jury of honour, however, has acquitted him. This artist did not adopt a safe plan; he should have got hold of a beautiful landscape photograph, the result of thought and clever selection by an educated photographer; no one would have blamed him then, as that sort of thing is considered all right.

Photography in colours once more and not a secret process, the whole being given to the world without fee or reward! See report of a meeting of the St. Helens Photographic Section. I did not hear of any picture being shown that had been executed by the process. We shall see what we shall see!

Mr. J. R. Sawyer's remarks about coloured light in dark rooms was quite to the point; in well-arranged works they do not stare at the light. In the first place, the workman has his work to look at; and, in the second, even if his eyes did wander, there should always be an opaque screen between them and the direct glare of the light. It is only our dark-room visitors who stare at the windows and say—"does not the light dazzle your eyes?"

FREE LANCE.

WHERE TO GO WITH THE CAMERA.

[It is hoped that this series of articles will be continued at regular and frequent intervals during the vacation months, and we shall be glad to receive contributions to the series from any friends able to treat of new and interesting ground.]

AMONG THE ALPS IN JUNE.

ALTHOUGH weather in Switzerland was very bad during July, 1883, we were fortunate in having seventeen perfect days among the Alps in June. The passage from Southampton to Havre on the night of the 19th was exceptionally smooth, and the journey was continued *viâ* Rouen, Paris, and Dijon to Lausanne without a break.

About four o'clock on Wednesday morning the train wound above the gorges of the Jura. Heavy mists clung to the pine-clad mountains, and the meadows were carpeted with forget-me-nots and what appeared to be narcissus. There is a solemn beauty about the Jura that is most impressive—"foresplendouring," as Carlyle would say, the greater glories of the high Alps. Lausanne, the last resting-place of Kemble, was reached about nine o'clock, and Ouchy shortly after, where we slept for the first time. The main features of interest at Ouchy are the old Clock Tower, the washerwomen (each standing at her tub), and the water-carriers; these are very picturesque.

Thursday was superb, and we left early by boat for Chillon. The old castle on the lake with its background of hills glowing with colour, between and above which rise the snow-clad mountains, formed a picture never to be forgotten even amongst the grander scenery of the Alps.

Eight o'clock next morning found us on our way through the Rhone valley, *viâ* Brigne, to Bel Alp. Skirting the lake we saw the railway to Glion (a mountain village) in progress. It is now open, and is said to be (excepting Vesuvius) the steepest railway in the world. The gradient is fifty-seven per cent., and the line nearly 700 metres long.

At St. Maurice we changed trains. There is half-an-hour's stay here. We did not see the fine grotto here, thinking half-an-hour insufficient. There had been heavy rain about three in the morning, so that the oppressive air of the Rhone valley was in as good condition as it ever can be with its miles of stagnant swamp. We saw the cascade of Pissevache; it was very full, and makes a beautiful plate. Near here is the Gorge du Trient, which also makes an interesting picture. Further up the valley, on the edge of a snow-clad giant, blushed the exquisite pink of the Alpine rose.

At Martigny the Rhone turns a sharp angle and accompanies the rail up the valley to Brigne, which we reached about half-past two. The porter of the Hôtel d'Angleterre speaks English as well as an Englishman, and, as a rule, the porters of the Swiss hotels all speak English. They accompany the omnibuses to meet the trains; therefore all you have to do, if you speak neither French nor German, is (having decided upon your hotel *before arriving*) to make at once for the right omnibus and address yourself in English to the porter.

After lunching at Brigne we started on foot to climb Bel Alp, some 7,000 feet. Crossing the Rhone at Brigne we soon began to ascend a bridle-path, which is very steep, and more or less a staircase of large stones. Here and there watercourses overflowed the path, rendering it muddy and disagreeable. Valais is a Catholic canton, and around the *châlets* on our way the dirt and mire were indescribable. We had not ascended far when we found the Turk's-cap lily, pink with red spots, growing abundantly. I believe it to be the martagon lily. As we ascended, the grandeur of the view rising behind us defies description. In the front a mountain torrent born of the snows above, Ben Alp, came rushing down, forming here and there beautiful pictures for artist or photographer.

At something over two hours and a-quarter we reached the half-way house. Here we had milk, and the horses fed on black bread. It was past eight in the evening when we reached the Hôtel Bel Alp. The air was quite frosty, and we were glad to take advantage of a large wood fire beside which to dine. It was too late to see anything after dinner, but next morning revealed one of the finest panoramas in Switzerland in a semicircle before us.

Wrapped in garments of eternal snow the mountains stood like saints in robes of righteousness. First came the Weisshorn, next the Matterhorn, the Mischabel, the Fletchhorn, Monte Rosa, and several other peaks. From the Sparrenhorn, three hours up behind the hotel, a more splendid view is obtained. Five minutes off is the "Maison de Tyndall," and certainly the professor has shown his appreciation of air, which we thought unrivalled. There are two hotels, both belonging to Klingele. The new one looks straight on to the great Aletsch Glacier—"the widest, the longest, and the grandest glacier of the Alps"—at once a marvel and a terror. The border line on the Eggischorn side—which seen from this great height appears a short walk—is fifteen miles long, and takes fourteen hours to traverse.

On the path to the glacier we found the yellow violets (*Viola biflora*), and round the hotel masses of *Gentiana verna*, *Gentiana acaulis*, violas of different shades, crocuses, *Toudonella Alpina*, myosotis, blue and white, and many other flowers unknown. I had with me a $7\frac{1}{2} \times 5$ camera, and here I took several plates—notably one of the Great Aletsch Glacier, which I thought good, but which was broken in going home. My bottles were each in boxwood cases, but, nevertheless, one bottle was broken to pieces. I used Kennett's slow plates. The exposure was generally nine seconds, the Alps being covered with a black card kept moving until the last two seconds. I received this hint from a gentleman of great Alpine experience, who advised the card in preference to a flap shutter.

All Saturday, Sunday, and Monday the Alps were cloudless. Finer weather could not be; and the sunrise on Sunday morning at Bel Alp will never be forgotten by those privileged to see it.

On Monday, June 25th, we went down to Brigue. Soon after leaving the Bel Alp Hotel we came to a fir wood gemmed with *Anemone var sulphurea*, and further on found *Authericum (Paradisia) liliastrum*—otherwise called "St. Bruno's lily." The word "*paradisia*" is very applicable to the purity of this flower, and it grew in profusion. We found several more flowers we knew, but the number of the beautiful unknown prevailed. Our horses having preceded us to Brigue, the *mâitre d'hotel* took upon himself to send a carriage to meet us at the bridge, which was fortunate, for we had not been five minutes in the hotel before a violent thunderstorm came on. Rain fell in torrents, and the lightning was magnificent. This storm cleared the air, and, as before, we had a cool journey through the Rhone Valley.

Leaving Brigue about seven next morning we reached Interlaken that evening about nine. Interlaken is charming. Nearly all the houses are built in *châlet* style. The shops are good, and the place is highly picturesque, bright, and clean. But I was disappointed in the Jungfrau as seen from Interlaken. How could it be otherwise after the grand panorama of Bel Alp—the Mischabel alone being fifteen thousand feet high? However, the weather was perfect, and on Wednesday we drove to Grindelwald, where I took several plates. I greatly regretted not having the camera with me at the Gorge of the Lütschine. The time was between nine and ten a.m., and the light was just right. We went to the lower part of the glacier, and there the fantastic shapes of ice made a wonderful picture.

Next day we drove to Sauterbrunnen. The road is very beautiful, the white Lütschine on one side and the pine-clad mountains on the other. At Lauterbrunnen, the "Staubbach," or dustfall, was full. It falls at one leap 980 feet, and it is so airy that a strong wind will blow it considerably out of its perpendicular. I got a good plate of it, and also of the Trümmelbach—a fall about a mile down the valley. There are, I believe, twenty-five falls here, and these two are the finest. The word "Lauterbrunnen" means "nothing but fountains." There are a quantity of trout in the Lütschine, and it seems a pity to serve them, as was done, before they were half grown.

Early on the 29th we started for Mürren. The bridle-path from Lauterbrunnen is steep, but not nearly so evil as the Bel Alp staircase. The view going up is magnificent. The Jungfrau, Mönch, Breithorn, and Eiger seem very near, and splendid pictures can be taken *en route*. Halfway up is a small inn, and close by the Staubbach takes her leap into the valley below. After two hours and a-quarter we arrived at the Hôtel des Alpes. It is a first-rate hotel, with a fine billiard-room and every luxury, even to a hairdresser. This hairdresser is an intelligent little man. He showed us over their museum, which is very interesting, and told us he often saw chamois on the black Mönch. He said the license had been raised to over four pounds, owing to the chamois having been killed down. They had two owls alive and several fine rough-coated St. Bernards. When one considers that all the velvet couches, chairs, pianos, &c., &c., have to be carried up these mountains there is room for astonishment. After a good second breakfast we left Mürren, and the following morning left Lauterbrunnen for Giessbach and on to Thun, which we reached on Saturday evening.

The Castle of Zähringen-Kyburg, with its four turrets, is most picturesque, and so is the principal street, which recals Chester. The Castle of Spiez, on the lake, makes a beautiful plate, with the Stockhorn and Niesen in the background. There are several other good pictures to be had at Thun, but the air is oppressive, which is a drawback. Being Sunday I did nothing, and next morning we left early for Berne. There is a beautiful view of the Alps to be taken at Berne. The mountains were clouded the day of our visit, which was a loss. The cathedral belongs to the old Ulm school of architecture, and dates from 1421. The stained windows of the choir are very fine, otherwise the interior is disappointing. The sculpture over the chief portal is the masterpiece of Erhard Kung, of Westphalia, towards the end of the eighteenth century. The face and figure of the Goddess of Justice are beautiful.

The clock tower makes a nice plate; but the bears which perform when the hour strikes are so small and dark that they do not come out well. The fountain of the ogre is another capital subject. We went to the museum to see the celebrated St. Bernard dog "Barry." He was a smooth-coated dog, and was considered A1 at the monastery. Rough-coated dogs cannot stand the exposure and are drafted away. This noble dog had saved fifteen lives. We obtained two photographs of him at the museum. "Barry's" interesting history and that of his successor is given in Vero Shaw's *Book of the Dog*.

We left Berne for Friburg in order to see the suspension bridge, which hangs on chains between two arches and vibrates with the tread, and to hear the great organ. M. Vogt (son of the late performer) played the celebrated thunderstorm, the *vox humana* interpreting the chorus of peasants. The organ has immense power, but lacks sweetness. Near the cathedral stands the lime tree of Morat. This venerable tree, fourteen feet in circumference, makes an interesting plate. The story goes that it was once a twig carried in the hand of a lad who ran into Friburg to announce the victory of Morat, in 1476, utterly exhausted. The boy fell dead with "victory" on his lips, and his twig was planted where he fell.

Our faces were now turned homewards, and we halted for the last time at Rouen. Near the station for Havre stands the modern church of St. Gervais. Here is a crypt of the fourth century. The church stands on the side of the old Priory of St. Gervais, where William the Conqueror died. A marble slab outside the church relates this. We went on to the Cathedral, which the guide-book mentions as "viciously florid," but Time has thrown his gracious mantle over the pile, refining and beautifying the whole. Inside we found the tomb of Rollo, first Duke of Normandy, and in the north aisle that of his son, William Longsword, assassinated in 944. Near the choir is the long-buried effigy of Richard Cœur-de-Lion.

For the first time rain fell on us in torrents and prevented an examination of the carving outside, so we hurried to St. Ouen's, the most ancient abbey in Normandy, founded by Clothaire I. in 533. The abbey was destroyed four times, and the present church was begun and almost completed during the fourteenth century, the west porch being the latest portion. The greater part of St. Ouen's is built of hardened chalk, which abounds in the district. The exterior of the abbey is most beautiful, being so harmonious that an idea of perfect unity is conveyed. The Portail des Marmousets, on the south side, will arrest the photographer.

I was disappointed with the nave, which is extolled as "pure Gothic;" and I afterwards found that Mr. Ruskin, in his *Seven Lamps of Architecture*, page 35, says of St. Ouen's—"Its nave is a base imitation:" whereas Mr. Freeman says—"Nothing is introduced which derogates from its claim to be the noblest of Gothic churches" *(History of Architecture*, page 399). The Norman tower, containing the *chambre aux clercs*, at the corner of the north transept is the only remains of the pre-existing churches. There are three exquisite rose windows—one the work of the master mason, Alexander Borneval, and another by his pupil, called "The Apprentice's Window." Berneval killed the lad out of jealousy, and was tried and executed. Master and pupil lie side by side in a chapel near the choir—date 1440. There are besides these windows 125 others. Near the western entrance is a black marble benitura, which reflects the nave in a striking manner.

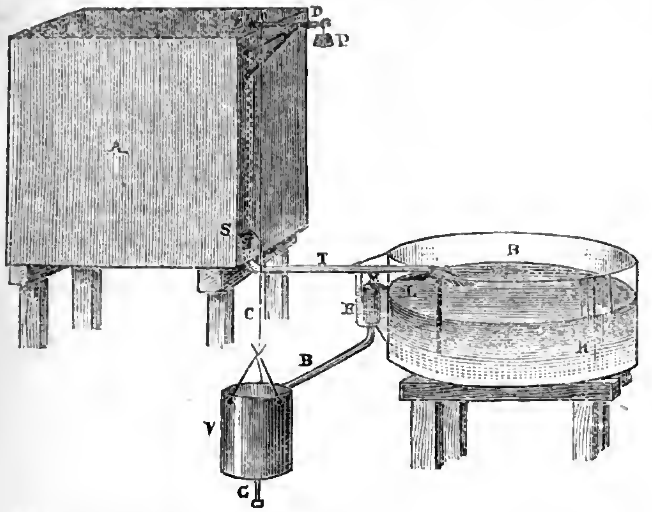
Passing by the wretched statue of *The Maid* in the Place de la Pucelle we came to the Hôtel Bourgtheroulde. The principal *bas-relief* represents the Field of the Cloth of Gold. There are also several salamanders and other sculptures. This hotel was begun in 1485, but not finished until the middle of the sixteenth century. The stone is a green grey.

From hence we walked to the museum of antiquities, where reposes the heart of Richard Cœur-de-Lion, the mark of William the Conqueror, a fine collection of faïence, one of the celebrated blue and white violins in delft, and much else too numerous to mention. Time did not allow us to visit St. Maclou—a most beautiful church, judging from the exterior; neither did we see the famous gradual of the monk Daniel d'Aubonne to be found in the public library. We much regretted not seeing the old houses that still exist—notably those in the Rue Malpalu, the Rue Nouveau Monde, and the Rue des Arpent, so attractively described by Mrs. Macquoid in *Through Normandy;* but time compelled, and we were soon on our way to Havre, from whence a smooth sea carried us back to the shores of old England. BOODE.

FOREIGN NOTES AND NEWS.

M. Berge's Print-Washing Apparatus.

Berge's washing apparatus, in which the water is automatically changed, forms the subject of an article in the *Photographische Correspondenz.* The washing apparati that have been described these last few years have generally been intended for the gelatine negative process, but this is for the removal of hyposulphite of soda from silver prints. Of course, the idea of washing prints automatically is by no means new, and there are already many more or less successful machines in the market; but there is always room for another. Every practical man knows how difficult it is to remove the hyposulphite completely from the prints, which have often, before that has been effected, to lie so long in water that their appearance suffers; and it is generally conceded that the quicker the washing can be done the better are the results. With this apparatus the prints may be thoroughly washed in from one to three hours. Description of the apparatus:—The apparatus can be set up any size suitable to the requirements of the establishment. The accompanying cut shows the arrangement according to the following proportions. In the cistern A, holding fifty-five litres, there is a vertical wire E S to which is affixed a valve S which permits the outflow of the water when the lever D is moved by the counterweight P. The water runs through the india-rubber pipe T into the washing vessel B. A very light bucket V, capable of containing about a litre, is hung to the arm E O of the lever D as near to E as possible, and at its under side an aperture of three or four mm. is made at G. A circular water-holder, B, of 0·4 of a metre in diameter, has a floor at H, and is connected by an aperture in its floor with the annex K. In the centre of this annex, 0·05 of a metre above the floor H, there rises the pipe R—the interior diameter of which is eight mm., and which carries off the washing water into the pail V. Above the pipe R a movable bell glass is inverted, the dimensions of which are so chosen that the washing water finds its way into it. In this way an intermittent outflow is established. The



gutta-percha tube T, which brings the water from the cistern A, is connected with a brass tube, which passes through the wall of the vessel B and empties itself in an oblique direction. The stream of water runs out with great force, and communicates to the water already in the vessel—a rotary motion by which the pictures are always brought in contact with fresh water. Mode of working the apparatus:—The cistern A is filled. The lever D E raises the valve S; the water enters the holder B by the tube T with a rapidity which can be regulated at pleasure. Since the aperture G in the pail is smaller than the opening M in the lever, the pail becomes filled, and when its weight is more than one kilogramme of water it exceeds that of the counter weight P; it thus causes the lever of E O to move backwards, and therefore causes the valve S to close, by which the flow of the water from the cistern A into the vessel B is interrupted, and the latter empties itself completely. Then when no more water flows into the pail V it will also empty itself completely, and thus become lighter than the weight P, which will again come into action and open the valve S, so that water can once more run from A into B. This filling of the holder B at M (the escape), as well as the subsequent emptying of the vessel, goes on repeating itself as long as any water remains in the reservoir A; and, of course, the greater the capacity of the reservoir, as compared with the receiver B, the oftener will the water be changed, and after each change of water the pictures are brought into contact with a perfectly-fresh supply. To convert the intermittent flow of water into a continuous flow all that has to be done is to remove the inverted bell glass at M. There is no fear of the water in B running over, because as soon as the water rises above the tube R the pail V is set in action, and cuts off the inflow of water from A.

THE ROYAL INSTITUTION.

The Freezing of Ether and Alcohol.

On Friday evening, the 13th instant, Professor Dewar gave an experimental lecture at the Royal Institution on *The Liquefaction of Gases.* Mr. Warren De la Rue presided. Among those present were Professor and Mrs. Edward Frankland, Sir William Bowman, Professor Tyndall, Lord Ranelagh, Professor Hughes, Miss Ottley, Colonel Pinney, Dr. Topham, Dr. Maudslay, Miss Emmett, Dr. Macpherson, Earl Percy, Captain Baillie, Dr. Tidy, Mrs. Ralli, Rear-Admiral De Kanzow, Mr. Dent, Mr. and Mrs. William Crookes, and Dr., Mrs., and Miss Edmunds.

Professor Dewar had arranged in the theatre a variety of pieces of apparatus for the production of extreme cold far below that obtainable by means of a solution of solid carbonic acid in ether. He first, however, drew attention to an iron vessel containing carbonic acid liquefied by pressure; when the carbonic acid was permitted to escape by turning a stopcock it chilled itself by expansion, and became condensed as carbonic acid snow, which could be handled with impunity despite its intense coldness, because it does not touch the hand, a layer of its vapour being always between the hand and the snow. This snow floated on the top of cold water, but when he compressed it into carbonic acid ice by a force of between one and two tons to the square inch, it sank in water, and gave off bubbles of gas freely. The ice could not be so easily handled as the snow. A solution of solid carbonic acid in ether gives a temperature of −80° Centigrade, which is the boiling point of carbonic acid; at this temperature mercury is frozen rapidly. By placing the mixture under the air-pump, to increase the evaporation, he obtained a temperature of −110° C., and he stated that −115 C. is about the lowest temperature obtainable by means of solid carbonic acid, which was the lowest temperature Faraday could obtain in the state of knowledge in his day.

In the lower temperatures now obtainable, he said, an air thermometer is useless for measurement, for air itself can now be liquefied by cold and pressure. The thermometer he used was, he stated, both simple and effective. It consisted of long, thin bands of copper and iron soldered together at the ends so as to form a thermo-pile. The soldered junctions of one end of the pile were kept at a constant temperature by being placed in water containing melting ice; the other end of the pile was put in the liquid the temperature of which had to be ascertained. The current from the pile passed through the coils of a reflecting galvanometer, which threw a vertical line of light upon a long white paper scale stretching all across the back of the theatre of the Royal Institution. The movements of this line of light along the scale indicated the temperature obtained in each experiment.

Liquid ethylene was the substance employed to produce the intense cold afterwards employed by the lecturer. About five pounds weight of it, under a pressure of 100 atmospheres, was stored in an iron bottle. His assistants had been about a fortnight making this quantity. They made it a little at a time and then put it in the large bottle, which stood in a vessel surrounded with ice and salt to keep it cold; for ethylene cannot exist in the liquid form above the temperature 10° C. Ethylene is the chief illuminating constituent of common coal gas, and burns in air with a smoky flame. The boiling-point of ethylene is −103° C., and by placing it under the air-pump a cold of −145° C., or −150° C., can be obtained. The following are the temperatures at which the gases named become liquid:—

Boiling Points Below the Freezing Point of Water.

	Boiling Point below F. P. of Water.	Boiling Point in Vacuum.
	Degrees Centigrade.	Degrees Centigrade.
Carbonic acid	−80	−116
Nitrous Oxide	−90	—
Ethylene	−103	−142
Oxygen	−184	−198
Nitrogen	−198·1	—
Air	−192·2	—
Carbonic Oxide	−193	—

The greatest cold yet obtained by man has been reached by two Russian physicists, Wroblewski and Olszewski, who by the use of liquid oxygen produced a temperature of −200° C. Hydrogen has been condensed into a mobile, colourless fluid; and although, chemically, hydrogen possesses the properties of a metal, in its liquid state it presents no appearance of metallic reflection.

The experiment of most interest to photographers was that in which Professor Dewar froze absolute alcohol. This was done by allowing some liquid ethylene to flow through a brass tube surrounded by solid carbonic acid and ether. When thus cooled it was passed into a large test tube, in the middle of which was placed a glass tube with a flattened bulb at the end, the bulb being full of absolute alcohol. The evaporation of the ethylene was then accelerated by the use of the air-pump, and the alcohol was frozen into a mass as clear and transparent as crystal. The tube containing it was turned bottom upwards, and as it melted it assumed exactly the consistence of glycerine, flowing in a sluggish way down the sides of the tube. Ether requires less cold than alcohol to freeze it, and in several of the experiments ether ice formed on the sides of the glass vessels; but Professor Dewar said nothing about its peculiarities, except that it interfered with the view of what was taking place inside the vessels. The warm air of the theatre was constantly condensing as snow or hoar frost on some of the vessels used in the experiments, and the chief difficulties of the lecture were the projecting of the experiments on the screen by the electric light so that all present might see what was taking place.

During the evening Professor Dewar momentarily liquefied oxygen. The lecturer also proved that ozone is a blue gas, which at a very low temperature dissolves in bisulphide of carbon, forming a blue liquid. As the temperature rises, the ozone oxidises the bisulphide of carbon with explosive violence. He said that there was no reason why some of these condensed substances should not be utilised for practical purposes—indeed, that there was no doubt they would be so utilised.

In the course of the lecture Professor Dewar called attention to the following table, the first column of which gives the temperatures at which the various substances are liquefied:—

Ranges of Physical Conditions.

	Point of Fusion.	Range of Liquid.	Range of Solid.
	Deg. C.	Deg. C.	Deg. C.
Water	0	370	273
Cyanogen	−34	158	239
Carbonic acid	−65	97	208
Sulphurous acid	−75	230	98
Ammonia	75	201	95
Hydric sulphide	−85·5	186	157·5
Nitrous oxide	−100	135	173
Chlorine	102	250	171
Carbon sulphide	−110	386	163
Hydrochloric acid	−112·5	163	160
Phosphorous chloride	−114	400	159
Ether	−117·4	413	155
Alcohol	130	365	143
Amyl alcohol	−131	410	139

RECENT PATENTS.

APPLICATION FOR PATENTS.

No. 9,359.—"Portable Stands for Photographic Cameras." Geo. Smith, Colebrooke-row, London.—*Dated June* 24, 1884.

IMPROVED METHOD OF PRODUCING SURFACES FOR PRINTING.
Specification of HARRISON GARSIDE.

This invention consists of an improved method of producing surfaces for mechanical printing by means of photography, and the object of my invention is the production, by mechanical and chemical means, of surfaces for mechanical or ink printing, and it is applicable to typographic, lithographic, and plate printing, and to the printing of fabrics by means of rollers.

Its leading feature is the breaking up of natural tints or photographic reproductions of the same into dots or lines of varying magnitude. This I effect in such a way that the so-called lights of the object to be represented are translated into minute dots or lines, and the shadows into dots or lines of such magnitude, and at such a distance apart, as almost to represent actual blackness.

One of the ways in which my invention can be carried out is as follows:—I produce a grained plate or mould by cutting or punching, in a flat metal or other plate, a series of shallow recesses of conical form and having their edges in close contact. From this mould I produce, by the method known as Woodburytype printing, a transparency on glass or thin paper, using such a mixture of fluid gelatine and pigment as will give absolute opacity at the extreme depth of the mould. I now copy this transparency in the camera on a suitable scale to give the grain desired in the printing block or plate. This grain may be conveniently varied to suit the different classes of work and printing. This copy, which consists of dots of absolute transparency, shading into absolute or nearly absolute opacity, may now be duplicated in any of the usual ways and for convenience in the form of films. If one of these grained films or screens be now applied to the face of an ordinary photographic negative it will be found on examination by transmitted light that the more opaque portions of the negative are now absolutely impervious to light, except in the form of minute spots, while the more transparent portions or shadows are veiled by a tracery of lines, which by suitable printing may be nearly obliterated in the further operations, while between these extremes the varying tints of the negative are seen as spots of varying dimensions. From the negative so adapted a photolithographic transfer may be made and transferred to stone or to a zinc or other plate if an etched surface for block printing be desired. If a surface for plate or intaglio printing be required the operations are the same, using in this case a photographic positive and reverse mask.

For certain subjects such as portraits, and in cases in which it is desirable to make improvements by hand, either mechanical or artistic, after the translation to grain has been made it is convenient to make an enlarged picture from the photographic negative and the grained film combined. From this enlargement, after the needed improvements have been made, a grained negative may be produced on the scale required.

I do not confine myself to the use of shaded dots in working my invention. For some subjects, such as the representations of machinery, statuary, and coins, shaded lines may be conveniently substituted, or a combination of two or more screens composed of shaded lines may be used as a substitute for the shaded dots.

The grained plate or mould may be also produced in various ways. For instance, a less mechanical translation may be made as follows:—

An exposed collographic plate is to be inked up with a tint approaching blackness and a grained resist transferred to a metal plate, or a similar transfer may be made by means of the grained paper which is in use by lithographic artists, or in other ways. The plate may now have a conical grain produced by repeated etchings, as practised in typographic block work.

In some cases it is convenient to produce the grain on the photographic negative in the first instance, by placing in front of the sensitive plate while exposed in the camera a grained screen, or by exposing the sensitive plate before or after exposure in the camera to the action of light under a grained screen, and in this case the exposure in the camera may be somewhat reduced.

My invention may also be carried out in the following way:—I expose a piece of sensitive carbon tissue under a negative, and after development I support it on a surface of soluble gelatine, and while still slightly soft I lay it upon a hard metal plate having the V-shaped grain and subject them to sufficient pressure to force the gelatine into the recesses of the plate; and I so proportion the thickness of the gelatine relief that the grain of the plate is entirely filled by the thickest portion of the relief when dry. I now dissolve the soluble support and produce a printing plate by electro deposition or in any other convenient way; or a piece of ordinary carbon tissue may be exposed and developed in the usual way and transferred to a white surface thickly coated with colourless gelatine or other slightly ductile material. While still in a softened condition it is to be placed in contact with the hard-grained plate, which may be waxed to facilitate removal and subjected to the necessary pressure. After drying the picture is to be removed, and it will be found that the tints are broken up into dots of varying dimensions in proportion to the varying thickness of the relief picture. From this picture a negative in black and white may be made, and a block or other printing surface produced by the usual means.

Instead of using a mask or screen consisting of shaded dots or lines, a mask composed of transparent dots or lines on an opaque ground may be used in the following way:—The mask is to be placed at an appreciable distance from the face of the negative which may be in contact with the surface to be impressed, and such a combination of direct and diffused light is to be thrown upon the mask as will cause the rays to disperse to an extent equal to very nearly the pitch of the dots or lines before reaching the sensitive surface.

Having thus described the nature and object of my said invention, I declare that what I claim and desire to be secured to me is—

1. The method of breaking up the tints of a photograph into positive dots or lines of varying dimensions, by means of masks or screens, consisting of shaded dots or lines substantially as described.
2. The method of filling up the grain of a plate by means of a gelatine relief for use as described.
3. The method of breaking up the tints of a gelatino-carbon or other relief picture by pressure in contact with a plate having a V-shaped grain.
4. The use and application of the above methods to the production of surfaces for ink and colour printing in all their branches substantially as described.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

At the technical meeting of this Society, held on the 24th instant, the chair was occupied by Colonel Stuart Wortley, Vice-President.

Several questions were read from the box. The first was—"During the prevalence of the recent east winds albumen paper prints have been found to become covered after drying with fine cracks upon the surface. What is the cause of this?"

Mr. Peek had noticed that this was the case particularly with those prints that had been treated with encaustic paste.

Mr. W. E. Debenham would have expected that filling up the pores with wax would prevent rather than cause cracking.

Mr. W. Davey attributed the cracking to the paper being allowed to dry up thoroughly after sensitising.

The Chairman, if he found a print cracking, would certainly try to improve it by using encaustic paste. East winds were generally dry, and for that reason would be favourable to the production of cracks.

The next question was—"If the time occupied for the transfer of an image from the eye to the brain were one-eighth of a second, will the photograph of a moving object, such as breaking waves, give so true a record of the impression produced if taken in a shorter time than the eighth of a second as it would if that were the duration of the exposure?"

Mr. E. Addenbrooke said that if each image took the eighth of a second to reach the brain and record itself, it did not follow that it was not succeeded by the next image appearing, although that might only be the thousandth of a second afterwards.

The Chairman inquired whether there was any evidence that one-eighth of a second was the time actually occupied in reaching the brain to produce an impression.

Mr. Leon Warnerke said that the time varied with each individual.

Mr. Peek would not use a very quick shutter to photograph breaking waves, but would prefer a rather slow one.

Mr. Debenham would use the quickest shutter that would give sufficient exposure to the plate. He had employed one for the purpose working in about the fiftieth of a second.

Mr. Peek would consider that a slow shutter.

Mr. W. Harrison agreed with Mr. Warnerke that the time for perception varied with each observer. In establishments, such as that at Greenwich, where astronomical observations were made the time for each individual using the instruments was noted and set down as his personal equation. In case of illness, however, the personal equation of the individual would be different.

Mr. Francis Cobb said that all the evidence was that from eye to brain the sensation was instantaneously transmitted. The eye has been known to shut, when a splash of ammonia was coming, in time to catch it on the outside of the eyelid and save the eye. From the brain to the hand in working a recording instrument some time was taken.

The next question was—"What is the cause of green fog? From the photographic journals it appears that this question is one that had been used in the examination of students at the City Guilds' Institute. If the cause has been definitely ascertained the writer wishes to know what it is."

Mr. T. Bolas said that some years ago Mr. Plener had found that one kind of green fog consisted of metallic silver. The fog mentioned lay between the film and the glass, and by removing the film from the glass with dilute hydrofluoric acid the fog could be got at. On rubbing it with mercury it was dissolved away.

The Chairman said that one form of green fog was upon the outer surface of the film and could be removed by rubbing. Possibly the kind referred to by Mr. Bolas might have been also removable by rubbing only, without mercury. That kind, however, was, he thought, iridescent fog, and liable to be caused by imperfectly-cleaned glass.

Mr. Warnerke handed round a negative which had become covered—except in a part which had been protected by a glass lying against it—with a deposit resembling green fog. This plate had been very carefully washed but not varnished, and he thought the lesson to be taken from it was that plates should be packed closer together for mutual protection.

Mr. Debenham considered that the iridescent stain in this case was due to sulphuration of the silver from an impure atmosphere, especially from one containing gas vapours. That it showed in the shadows of the negative was not contradictory of this view, as the plate was a little veiled, and any want of clearness indicated the presence of a certain amount of silver.

Mr. C. Ray Woods said that green fog was not often heard of before manufacturers had made their plates much more perfect than they had formerly been produced.

The Chairman replied that he had noticed green fog in his earliest experiments, before any plates were commercially made at all.

Mr. Debenham said that in Mr. Bennett's first published formula green fog was mentioned, and certain precautions referred to in order to guard against it.

The Chairman continued that if a certain plate were brought with some details respecting it, and he was asked what was the cause of green fog in that plate, he might suggest an answer, but that the question could not be answered in the general way without regard to the particular case.

Mr. A. Cowan expressed himself similarly.

Mr. Warnerke said that green fog was unknown in Russia. He thought that this was due to the dryness of the atmosphere.

The Chairman had observed that plates newly made might give green fog, but if kept for some months in a dry atmosphere the tendency went off.

Mr. Woods said that green fog could not be obtained with iron development unless some solvent of silver bromide were present, such as hypo. or ammonia.

Mr. T. Sebastian Davis said that at a former meeting he had complained of a want of density in his negatives, and it had been suggested to use a much greater quantity of bromide in development. He had done this with complete success, using the following formula:—

Pyrogallol	2 grains.
Water	½ ounce.
Ammonia, ·880	2 minims.
Potassium bromide	4 grains.
Water	½ ounce.

Mix, and apply to the plate. This was eight times the amount of bromide he had been using previously. The time of development was increased, but not the time of exposure.

Mr. Woods generally used two grains of bromide to one of ammonia.

The Chairman thought that when increasing the dose of ammonia during development it was wise to add a little pyro., otherwise that constituent might become exhausted.

Mr. Cowan said that it was asked some time ago whether it was better to mix the developer all at once, or to add the ammonia little by little. He found that by the latter treatment he could get a good, bright picture on a plate that, when the whole developer was mixed at once, would only give a poor, foggy result. He produced two negatives, one developed in each way. The difference was very strongly marked.

The Chairman said that development was a science. He could teach anyone to make plates, but not to develope.

Mr. Cowan said that a letter had recently appeared in one of the photographic journals asking whether there was any injurious effect upon the brightness of the image from using a very small stop, and that Captain Abney had written on the same subject. He (Mr. Cowan) produced two negatives on the same plate, one of which had been taken with an ordinary stop, and one with a stop measuring only $_{2}f/_{50}$, requiring an exposure of nearly 4,000 on the universal system. There was no loss of sharpness from diffraction, and no difference in brightness in the two results obtained.

Mr. Debenham referred to a negative of a statue taken by Mr. A. L. Henderson, at Southampton, with a pinhole, meaning $\frac{1}{120}$th of an inch, and no lens. There was no lack of brightness in the picture.

Mr. Cowan said that that picture was a trying test, as it was of a white statue against dark trees. There was no effect of diffraction visible, and the inscription on the pedestal, although coming out very small, could be distinctly read.

Mr. Woods said that if such an opening were used in photographing the sun, diffraction would come in.

The Chairman had used very small stops in taking views without any injurious effect.

Mr. Davis showed a printing-frame of large size into the centre of which one of Mr. Warnerke's sensitometers had been fitted, so that a large plate might be tried instead of having to cut it.

Mr. George Smith showed a tripod stand on the general principle known as Kennett's, but it was improved by having on the side of the lower or single part of each leg a piece of wood screwed. This wood was broad but thin, and served to increase the rigidity of the stand, which was very light, weighing less than a pound and a-half.

Mr. Warnerke showed some very fine photographs of the interior of a palace at Moscow, taken by a friend of his. The negatives of these photographs had been much over-exposed, but had been treated before development by immersion in a ten-per-cent. solution of bromide of potassium, which had had the effect of producing perfect negatives. He mentioned also that the plates were of an exceedingly-rapid make, giving 25 on the sensitometer. He thought that this would prove that rapid plates were not necessarily deficient in quality.

Mr. Debenham inquired whether the plates would have given as fine a result if they had had only their normal exposure and been developed in the usual way.

Mr. Warnerke believed that they would.

The meeting was then adjourned.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on Thursday, the 19th instant, the chair was occupied by Mr. W. H. Prestwich.

The discussion upon Mr. W. Coles's lecture—*On Altering the Density of Gelatine Negatives* (which at the preceding meeting had only been carried as far as the reduction of intensity)—was resumed on the question of the various methods of increasing density.

Mr. W. E. Debenham said that the method referred to by the lecturer, of using a solution of Schlippe's salt after treatment with mercury, was the one which he preferred and regularly used. He did not find, when used after the iodide solution of mercury, the colour so red as to be objectionable. After a bichloride solution the colour of the negative certainly was red, but that was not the course of proceeding he adopted.

Mr. W. Coles replied that the negatives were not so red in colour when hypo. was mixed with the mercuric solution—in the formula of Mr. B. J. Edwards, for instance.

Mr. A. Cowan considered Dr. Monckhoven's method with cyanide of silver to be the best.

The Chairman used bichloride of mercury, followed by ammonia.

Mr. A. L. Henderson preferred the use of lime-water, instead of ammonia, after bichloride of mercury. When using silver as an intensifier he always found the negative became eventually stained. These stains did not show in the first instance, but came out as spots afterwards.

Mr. Cowan advised the plan of getting sufficient density or some excess in the first instance. He considered it easier and better to reduce intensity afterwards than to add to it.

Mr. W. M. Ashman formerly intensified with mercury followed by ammonia. All those negatives which had been thus treated were now much stained. He had also used mercury followed by ammonium sulphide, and this had given permanent results. He produced examples of both methods.

Mr. Debenham remarked that the ammonium sulphide very much resembled in its action that of Schlippe's salt, but its horribly-offensive smell was an objection to its use.

Mr. Ashman added that those negatives in his possession which had been intensified by silver were now useless.

With reference to one of the experiments performed by Mr. Coles, and to a question proposed by him at the preceding meeting, a letter was read from Mr. T. H. Norris, as follows:—"I have been trying some experiments with hypo. and ferric chloride, and find that when $Fe_2\,Cl_6$ is added to hypo. in small quantities there is a precipitate which I have analysed, and find is oxide of hydrated oxide of iron (ferric), and no sulphur is thrown down if solutions are neutral. If solutions are made corresponding to—

$$\underset{325}{Fe_2\,Cl_6} + \underset{248}{Na_2\,S_2\,O_3\,5\,(O\,H_2)},$$

these, when mixed in equal quantities, give no precipitate, and there is a certain quality of ferric chloride left; but if three of Fe to four of hypo. the solution gives a precipitate, and the iron is *completely* converted into *ferrous*. There is no sulphate formed, and, no doubt, the reaction is the following:—$Fe_2\,Cl_6 + 2\,Na_2\,S_2\,O_3 = Fe_2\,Cl_4 + 2\,Na\,Cl + Na_2\,S_4\,O_6$; but, considering there are many more sulphur acids than these, perhaps it may be converted into some of the following:—

$$(Na_2\,S_2\,O_3)$$
$$Ns_2\,S_2\,O_6$$
$$Na_2\,S_3\,O_6$$
$$Na_2\,S_4\,O_6$$
$$Na_2\,S_5\,O_6$$

I will try and make some more experiments before the 26th. I think of being at the London and Provincial Photographic Association that evening.—Yours, very truly, T. H. Norris."

The Chairman, in commenting upon Mr. Coles's lecture and the discussion which had ensued upon it, expressed himself as indebted to the lecturer—a sentiment which was supported by a very hearty vote of thanks on the part of the members.

Mr. Norris sent samples of a material called "vulcanised fibre," which had been applied to the use of the photographer as the material of which to form the sliding shutters of dark slides, and which, it was suggested, might be advantageously employed for other photographic purposes.

Mr. Cowan showed two negatives of the same subject, one of which had been developed in the usual way with pyro. and ammonia, and the other by Mr. Munro's formula with carbonate and sulphite of soda and carbonate of potash. The latter gave rather more intensity of the two. He thought, however, it suited slow plates better than quick ones, and was worth further experiment.

Mr. Henderson said that he had brought with him the diffraction-grating lamp of which he had spoken at a previous meeting. His experiments with it, however, since that time yielded the most perplexing results. Sometimes it had given similar results to that which he had mentioned before; at other times the results from the diffracting and from the plain glass appeared about equal. In one instance the light through the plain glass had given the fainter indication of the two on the sensitometer.

Mr. Debenham thought that this pointed to the probability that the differences which had been observed were due to some extraneous unnoticed differences of conditions, and that the diffraction grating itself had had no influence in producing the result. As had been observed by Mr. W. K. Burton and himself a slight pre-exposure to light would cause a plate to register many degrees higher on the sensitometer, and if some of the plates used had been more exposed to the light of the coating-room than others that would be one possible way of explaining the differences in the results referred to by Mr. Henderson.

Experiments were then made in an adjoining darkened room with the lamp, with and without the interposition of the diffraction grating. The differences in the results obtained appeared to be slightly in favour of the use of the grating, but were so small that they were not considered in any way decisive.

Mr. W. K. Burton proposed a question for discussion—"What is the best proportion of bromide to be in excess in making an emulsion?" He said it had formerly been recommended to use the silver and the bromide nearly in their equivalent proportions, but lately the proportion of excess of bromide that was advised had been very largely increased. He thought that this had been carried too far.

Mr. HENDERSON had successfully used equal weights of silver and bromide, and had even gone so far as to use one and a-half part of bromide to one of silver. On the question of obtaining density he (Mr. Henderson) said that great density could be gained by adding meta-gelatine, sugar, or glycerine to a finished emulsion, but the addition caused a tendency to fog.

Mr. BURTON thought that density in the boiling process was favoured by the use of a large quantity of gelatine with which to boil.

Mr. J. B. B. WELLINGTON, in making an emulsion by a cold emulsification process, found that by keeping in the cold state for some hours before adding the gelatine the bromide passed into the blue state, but gave scarcely any quicker plate than if used at once, when the emulsion remained red throughout.

Mr. DEBENHAM's experience was similar to that of Mr. Wellington's.

Mr. HENDERSON contended that rapidity did accrue from keeping before adding the gelatine.

SHEFFIELD PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held on Tuesday, the 10th instant, at the Masonic Hall,—Mr. Councillor Firth in the chair.

A large number of members were present, there being a very attractive programme for the evening, namely, the pictures and talk of the trip to Dovedale, and the pictures in competition for the subject composition of *A Rustic Bridge*, two prizes having been offered by the committee—one for the best in half-plates and under, and one for whole plates and over. Many members took part in the competition, and a very beautiful variety of bridges were portrayed, yielding a pleasant and interesting exhibition for the non-competitors as well as the competitors. The collection embraced most of the picturesque bridges in the surrounding country.

The prize for whole-plate and over was won by Mr. Firth (President) for a very brilliant picture of the rustic bridge at the entrance to Dovedale. Mr. Thomas Hibbert (one of this season's "colts" in the art) managed to "pull off" the prize for half-plate and under, with a very carefully-selected and interesting representation of the wooden foot bridge near Rivulin paper mill.

Many of the pictures were beautiful and highly creditable, and in one or two cases ran very near the winners in the ballot box.—Mr. H. Rawson showed a stereo. picture of fine manipulation and poetic subject.—Mr. B. Wood exhibited an enlargement by the Autotype Company from a negative of a rustic bridge in Padery Wood, which called forth great praise (not for competition).—Mr. T. S. Yeomans showed a very beautiful cabinet vignette of *Rustic Bridge, Foliage, and Rippling Brook*, carefully selected and rich in tone.

Mr. W. DAKIN drew the attention of the members to the high qualities of a developer he had mixed and tried (which was some time ago published in THE BRITISH JOURNAL OF PHOTOGRAPHY and *News)* and worked with great success on both in- and out-door pictures, but which he said was invaluable for outdoor work and amateurs, as a protracted development did not stain the film, there being no ammonia in it. The formula runs thus:—

Carbonate of soda	125 grains.
Carbonate of potash	125 ,,
Sulphite of soda	125 ,,
Water	10 ounces.

Use pyro. as usual to the respective sizes of plates, and enough of the above solution to flood with.

Mr. H. RAWSON brought a few dishes made by the Patent Pulp Company, which were white, and seemed very likely to be of great use in the art, having the requisite chemical-resisting properties, along with durability and cheapness.

The subject of the next trip was then brought on, and Miller's Dale was selected.

Mr. Drummond was elected a member.

The subject of Dovedale, and the pictures got there, then formed the topic of conversation, the trip having taken place on the 22nd ult. on as fine a day as such an assembly could desire. The party numbered twenty-two, starting with their valuable baggage from the Midland Station at 6-30 for Cromford, and landing there about eight, where, as per arrangement, two waggonettes were waiting to convey the party the remainder of their most delightful journey. The route was through Cromford, which is a very interesting as well as picturesque little place, leading up to one of the Edens of the Peak, the "Via Gellia," through which no man having a love for art or for Nature's grandeur could pass without its kindling in his breast more pleasure and gratitude than his language could possibly express. The sun, by the time the *voyageurs* had got fairly between the two grand hills, was high enough to throw its brilliant rays along the varied foliage of the valley, and light with vivid whiteness the peaks of limestone rocks which here and there broke through the wooded clothing of the hills, making pictures which changed every turn as the horses sped along through the winding road. The sweet scent of the lime bloom, mingled with the bursting hawthorn, rendered the air a perfect stimulant to the party of picture hunters. There is, too, a rippling brook which runs through the dale, and which varies the near pictures by first running on one side of the road and then on the other, but all the way being lined abundantly with forget-me-nots and pretty wild flowers of many colours. After running for about five miles through this glorious country we came on a more barren part—the termination of the High Peak Railroad—where a short time was allowed for the refreshment of man and beast. A clear run was then made through the Isaak Walton, which is situated at the entrance to Dovedale. All arrived safe, and delighted with the prospects before the party.

A bright sun, a clear atmosphere, a country around rich in charming pictures caused very little time to be lost before men and apparatus were seen taking different directions for work. There were thirteen cameras, and 112 plates of various sizes were exposed. Many of the members took up the dale, and the most experienced and careful of picture-hunters were delightfully surprised at the wild beauty around them. Nothing can surpass the romantic wildness and luxuriant verdure of the hills, the view embracing the river Dove, so clear and sparkling, and so richly reflecting the dark green and pointed tops of the majestic firs and larch, mingled with the feathery foliage and graceful drooping of the silver birch, with here and there standing out in bold relief gigantic pillars and cones of limestone rock, dotted with patches of dark-green moss, and bearing from their giddy height festoons of ivy and other creeping plants, which cause this spot to look as if some tasteful mortal had displayed his tact to make the place sublimity itself, rather than the result of ordinary law surrounding common things. Plate after plate in quick succession received its charming imprint, and many were the sighs and exclamations of—"Oh! I hope that will come out all right! It is a beauty!" It must be admitted that many have justified the expectations formed.

Mr. Thos. Firth, who worked the whole length of the dale with whole-plate camera, is well repaid for his trouble with some excellent pictures.—Mr. Taylor also succeeded in getting some choice views.—Mr. H. Rawson, armed with a new stereo. fit-out, secured some charming "bits" of river, rocks, and trees.—Mr. W. B. Hatfield worked a long-range lens on whole plates, and was very successful.

Mr. Dakin and Mr. Milward left the party with the object of varying the collection of pictures, and went to work at Ham Hall and grounds, which stood a short distance from the dale, nicely surrounded with majestic timber and sufficiently high up the hill to impart to it a picturesque prominence over the surrounding country. After obtaining permission from the owner—who gave it in a good-humoured and welcome fashion—they commenced work. Mr. Dakin got five 10 × 8 negatives from choice positions, and with a success that has left nothing to be desired. They are among the finest the writer has ever seen as regards detail, contrast, and selection. Through some accident with Mr. Milward, when changing his box, his work was spoilt.

Messrs. Turner, Wood, Pilley, Mottersham, and Pearse all brought home some lovely things; and, taking one thing with another, the day was one of the best the Society has ever had.

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

THE unsettled weather of Monday and Tuesday had been regarded with some little anxiety by those members of this Society who were intending to join the annual excursion to Edzell, on Wednesday, the 18th instant; but the more promising state of the weather on the morning of that day, along with the fact that the weather forecast of the district promised "some rain," entirely relieved the minds of those interested. A party numbering over sixty, composed of the members of the Association and their friends, left Dundee East Station at 9.15 a.m. Through the kindness of Mr. Hunter, station-master, a couple of special carriages had been ordered through from Glasgow for the occasion, and this materially added to the comfort of the excursionists.

Arriving in Brechin at 10.45 the party found five brakes in readiness to convey them to Edzell, which was reached after an exceedingly-pleasant hour's drive, without more than a few minutes' delay for slight refreshment. Most of the party arrived with cameras of all dimensions—from quarter-plate up to the size playfully alluded to as "dog-kennel"—and walked along to Gannochy bridge, the picturesque glimpse from which was the signal for commencing the attack. Proceeding up a path which ran beside the river there were also presented to the view numerous subjects for the camera.

Returning to Edzell at 2.30 p.m. every one did ample justice to a first-rate dinner purveyed by Mr. Keith Knowles, of the "Tanmure Arms," after which a start was made for Edzell Castle, a short distance from the village, where an hour was pleasantly spent and several more pictures taken. The total number of plates exposed during the day was about 120. After tea a couple of photographs of the party grouped round the front of the hotel were taken by Messrs. Johnston and Geddes; and at twenty minutes to six the return journey was commenced and Dundee reached at 8.45 o'clock, after a most agreeable day's outing, which was thoroughly enjoyed by all present.

DERBY PHOTOGRAPHIC SOCIETY.

A MEETING of this Society was held at the London Restaurant, Derby, on Wednesday, the 18th instant,—Mr. R. Keene, Vice-President, in the chair.

The minutes of the previous meeting having been read, the following gentlemen were declared duly elected:—As honorary members: Messrs. R. J. Billinton, Henry Bolden, George Rice, and W. W. Winter. As members: Messrs. F. Campion, J. Crossland, E. A. G. Jewitt, J. Merry, and R. L. Warham.

The CHAIRMAN then read a proof of the proposed rules. After a discussion, during which several alterations were made, the amended copy of the rules was unanimously adopted, on the motion of Mr. A. J. Cox, seconded by Mr. H. A. Bemrose.

The first technical meeting of the Society was fixed for Wednesday, July 2nd, when a paper will be read by Mr. R. Keene.

After the usual vote of thanks to the Chairman the proceedings terminated.

The following are the officers of the Society:—*President:* Captain W. de W. Abney, R.E., F.R.S.—*Vice-Presidents:* Charles Edward Abney, B.A., H. Arnold Bemrose, M.A., and Richard Keene.—*Committee:* Arthur J. Cox, James E. Kaye, and Thomas Scotton.—*Hon. Secretary and Treasurer:* Fred. W. Simpson.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

An ordinary meeting of the above Association was held on the 18th April,—Professor Vogel in the chair.

A letter was read from a correspondent in Holland complaining that of a number of photographs mounted at one time—some on black and some on white mounts—those on black mounts had become spoilt, while those on the white mounts remained in good condition.

The Chairman gave suitable advice.

A letter from Dr. Browski, dated Mossul, Mesopotamia, was then read, after which a landscape said to be taken by moonlight, by Herr Zang, of Sonnenburg, with an exposure of thirty-five seconds with the full aperture of a Voigtländer thirty lines rapid lens, was exhibited. The landscape was somewhat under-exposed, but the moon itself was over-exposed.

Herr Schultz-Hencke remarked that he had taken photographs by moonlight with the moon behind him and shining on the objects taken, but that he had required an exposure of eight hours.

Herr Anschütz showed a number of instantaneous pictures of landscapes, men, and animals.

Herr Godeljce, of Leyden, exhibited a number of instantaneous landscapes and sea views.

The Chairman communicated a very simple means of purifying gelatine with which to make emulsion. He is convinced that by employing this process almost any gelatine can be used for the preparation of emulsion.

Herr Joop expressed his opinion of what photography in general and heir Association in particular owed to Professor Vogel, and mentioned hat they had just founded a prize of 1,000 marks (say £50) which they would award to him as a token of their appreciation of his services.

After the applause which followed had subsided,

The Chairman returned thanks in a suitable speech, in the course of which he said he had been called, in no complimentary sense, a theorist as opposed to a practical man; but he thought the best practice was founded upon true theory—at least his practical process was based upon his theories. He (the Chairman) then described his new process. [This description has already appeared in The British Journal of Photography.]

Herr Joop recommended a method of purifying the silver bath to be used nstead of the usual process with permanganate of potassium.

The contents of the box were then dealt with, after which the meeting was adjourned.

Correspondence.

THE EFFECTS OF RED AND YELLOW LIGHT ON THE EYES.

To the Editors.

Gentlemen,—I see that the subject of light for the operating-room is still occupying public attention, and that the champions of the greenish-yellow medium—notably Mr. W. E. Debenham—are still busy lauding and recommending their special fancy. To Mr. Debenham, as I believe, is due the credit of having started the investigations into the matter; but I also believe that Mr. Debenham took for his original text the assertion that red light is more hurtful to the eyes than yellow. I held a different opinion, and stated, in your issue of May 9th of this year, that yellow light was more hurtful than red light. Had this statement rested on my word alone I should have expected that some sort of denial or contradiction would have been forthcoming even in ordinary courtesy; but, when my statements are supported in the most plain and direct language by two medical men—one an ophthalmic specialist of repute—it appears to me to be incumbent on my opponents to notice at least my objections to their arguments, and, before proceeding further, to prove that my medical authorities and I are wrong.

My assertion is—Yellow light is more hurtful to the average human eye than red light. I am backed by the only medical men I have consulted, and I appeal to your readers to say whether or not I deserve any attention. If I am right, or remain uncontradicted, what is the use of hunting the "greenery-yallery" colour to death? Much good has been done by Mr. Debenham and his associates; new light has been thrown on several subjects; but if our eyes are to be losers instead of gainers by the innovation it would be better if we had "let well alone." To me the matter seems of sufficient importance to warrant an appeal to a jury of ophthalmists. At present the question stands thus: Dr. Herschel and Mr. Ackland *versus* Mr. Marcus Gunn and Dr. Pringle.—I am, yours, &c.,

Craigcleugh, June 23, 1884. Andrew Pringle.

P.S.—In my letter addressed to you last week I see I have overstated the membership of the Photographic Society of Great Britain, and also the expense incurred in the publication of that Society's *Journal*. The membership in February this year was under 400, and the *Journal* expenses do not amount to £100, as from the £115 of outlay £76 have to be deducted for income. When I wrote I had not at hand the balance sheet of the Society, and I am to blame for not being more accurate.—A. P.

PHILADELPHIA AMATEUR PHOTOGRAPHIC CLUB.

To the Editors.

Gentlemen,—In your issue of May 16th I notice a letter from Mr. Beach, in which he states that the "Society of Amateur Photographers of New York" is the first to give its members dark-room and experimental facilities. From the expresssion used one would suppose he was referring to the entire country.

Our Club, as above, was formed December 21st, 1883, and a *suite* of rooms procured early in February, where we give our members all facilities necessary. We now have a reading-room furnished with all photographic journals, as well as a library of about one hundred volumes, a dark room with twenty-five closets for individual members, and also an ample sink-room with four taps, allowing eight members to work at one time. There is a printing-room, with an unobstructed southern exposure, containing burnisher and sensitising apparatus, and windows arranged with exterior platforms for frames. A small room, not yet furnished, is to be used for emulsion-making or other experiments.

We now have about forty active members, and are receiving applications so rapidly that we fear in a short time we shall be compelled to limit our membership, owing to the encouragement given us. The want of such a club was felt, and we do not wish to be classed as having followed the ideas of others.

Trusting you will correct Mr. Beach's claim,—I am, yours, &c.,

907, *Filbert Street, Philadelphia, June* 12, 1884. Geo. W. Pearson, *Secretary.*

"ON ALBUMENISING PAPERS."

To the Editors.

Gentlemen,—We have read with great interest the correspondence and leading articles which have appeared lately on albumenised papers and albumenising, &c. We beg to say that, so far as our long experience goes, we have always advocated the high salting of the pure fresh-egg albumen and strong silver solution for sensitising the same, so as to secure, as far as the quality of the negative will allow, a good body of silver in the pictures to tone, fix, &c. Assuming the prints were thoroughly washed there would be a fair chance of permanency. This cannot be obtained with weak salting or sensitising solutions.

In last week's issue you mentioned seven and a-half grains of chloride per ounce, and silver bath sixty grains. For years past we have prepared our papers with that amount of chloride, and have recommended a sixty to sixty five grains' silver bath. We beg to enclose you samples of papers so prepared for your inspection or trial.—We are, yours, &c.,

Willesden Green, N.W., June 24, 1884. A. Rivot and Co.

Notes and Queries.

George Darnsley wishes to be informed what is the difference between the "ivorine" of 1884 and the translucent medium formed of gelatine and a white pigment which was employed eight or ten years ago, by the late Oliver Sarony, as a basis on which to mount his carbon prints.——We reply to this by saying that we do not know.

"Can I copy a lithographic portrait published by a Boston (America) firm? It is not stated on the print that it is copyright.—Querist."——In reply: As it is imperative in the United States to imprint upon all copyright works the fact of their being copyright, we do not imagine that, in the absence of such announcement, there is any legal difficulty in the way of copying the portrait specified.

W. H. Harrison says:—"Your paragraph, in the last number of the Journal, speaks of care in mixing chlorate of potash and sulphide of antimony by means of a bone knife; but please allow me to point out the deadly danger of an incautious person triturating the two together in a *mortar*, should he do so in ignorance. The mixture is far more energetic than gunpowder, and is explosively ignited by friction. Once I burst about half-a-dozen toy cannons with it, which were quite safe when charged with gunpowder to the muzzles."

Rev. J. Brown wishes to know what is a suitable solvent for bitumen when it is to be employed for photographic purposes, such as coating a metallic plate for photo-engraving.——We reply: Benzole and oil of turpentine, both singly and mixed, have been successfully employed. In order to obtain greater clearness of the image it has been recommended to add certain essential oils, such as oil of lemons. If our correspondent have access to the work on this subject by Niepce de St. Victor, which was translated into English many years ago, he will find much useful information given in detail.

R. T. Watson has found, when photographing an interior on a 12 × 10 plate, that instead of there being only one window in the negative, as is the case in the natural subject, there are two—the original and proper one, accompanied by another which is fainter and upside down.——This is a special class of ghost picture which not infrequently accompanies the employment of lenses of the "rapid" class. It is caused by reflection from the inner surfaces of the lenses, by which a non-inverted image is formed. The remedy consists in altering the distance between the front and back lens of the combination.

"Can you inform me of any simple method within the powers of a young and inexperienced photographer by which I can ascertain whether my lens has a chemical focus? I invariably get a beautiful and sharp image upon the ground glass, but when I take a negative of any scene, no matter how sharply it is focussed, the negative never possesses the same degree of sharpness displayed upon the ground glass. My camera is made by ———, which may be considered as a guarantee that the fault does not lie there, but with the lens, which a friend informs me must have a chemical focus, whatever that may be.—Cymbria."——In reply: By the term "chemical focus" is meant that the lens is not properly corrected for colour, owing to which the visual image seen on the focussing-screen is brought to a focus nearer to or farther from the lens than the plane upon which the chemical rays find their focus. To ascertain if the lens, in the case mentioned, possess this property, focus very sharply, employing a large stop, upon bold printed matter situated at a distance of a few hundred feet (signboards or showbills answer the purpose quite well), and take a negative. Then push in the ground glass towards the lens about a-quarter of an inch, by which the image will be out of focus visually, and expose a second plate. Lastly: withdraw the ground glass from the lens a-quarter of an inch beyond the point of best visual focus and expose a third plate. If the second picture be sharpest then the lens is under-corrected, over-correction for colour being proved by the third image being best defined.

"KINDLY permit me, through the medium of your useful *Notes and Queries* department, to submit a case to my fellow-photographers. I have access to a window, nearly opposite to which, at no great distance, is a corner of a street which is bifurcated, and at which many actors, artists, and leading men of the day take occasion to stand for a few moments when bidding each other "goodbye" previous to passing each on his own way. I have already succeeded in obtaining several instantaneous groups in the utmost perfection, in which the figures are small; but I am thinking of obtaining a large lens of long focus for the special purpose of taking these figures on a scale of about four or five inches. Previous to incurring this expense, which will be considerable, I desire to know if I should be justified in offering such groups for public sale, or have the persons composing these groups the power of preventing such sale. If they have, then might not such power also be possessed by any recognisable individual whose portrait, as one of the multitude, appears in any ordinary street, boating, racing, foundation-stone laying, or other similar view to which the camera has been directed? Soliciting replies—I am, yours, &c., ALPHA."

Exchange Column.

Wanted, THE BRITISH JOURNAL OF PHOTOGRAPHY for 1879, bound or unbound, in exchange for $4\frac{1}{4} \times 3\frac{1}{4}$ gelatine plates.—Address, EDWIN DODDS, Church-road, Low Fell, Gateshead.

Wanted a good 5 × 4 or half-plate lens, in exchange for either four-lens repeating-back gem camera or Victoria camera, takes four on a quarter-plate.—Address, A. HOPKINS, 21, Bartholomew-street, Exeter.

Wanted, a stereoscopic camera and slides, in exchange for a $3\frac{1}{4} \times 3\frac{1}{4}$ sciopticon camera, rolling-press with glass bed, lantern slides, or scores of photographic things.—Address, W. J. CHADWICK, Eccles, near Manchester.

I will exchange a quarter-plate lens, black stand table, *carte* burnisher, new, small ash chair, nearly new, for a chair with changes and exterior background.—Address, WM. BREWSTER, photographer, 3, Charles-street, Preston.

I will exchange a midget camera, with six lenses, as good as new, two slides, one quite new, by Marion, for taking twenty-four midget pictures on one plate, in four positions, for anything useful.—Address, W. W. WINTER, photographer, Derby.

I will exchange a good five-chambered repeating-revolver, in mahogany case, fitted with powder flask, for an interior background, or a good set of curtains fit for studio, or anything useful in photography.—Address, J. S. WALKER, 48, Wellington-street, Woolwich, S.E.

Wanted, a first-class rectilinear or symmetrical lens and bellows-body camera, about $8\frac{1}{2} \times 6\frac{1}{2}$ or 10 × 8, in exchange for a fifty-two-inch half-plated Timberlake bicycle, used only a few times, quite perfect, cost with extras over £16.—Address, W., 2, Claremont Cottages, White Hart-lane, Barnes, S.W.

I will exchange a nearly-new eight and a-half-inch square bellows-body folding camera, in perfect condition, with two single- and four double-backs, for a modern half-plate square ditto, with double- and single-back, and a good lens; inspection allowed and required.—Address, JNO. STORR, Westgate-on-Sea.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPH REGISTERED.—

Frederic Gorham Tirehurst, the Old House, Battle.—*Photograph entitled "Clubs is Trumps."*

J. W. V.—Any dealer in photographic requisites will get the burnisher repaired for you.

S. J. WEARE.—See article in the present number. This will give the desired information.

AMATEUR (Bradford).—Either Nos. 1 or 2 on your list will answer better than the others. We employ No. 2.

LEROY.—For purely line subjects the bitumen process will be the best. For half-tone the gelatine must be employed.

LAUNCELOT GUBBINS.—The phosphate of soda toning bath, as given on page 230 of our ALMANAC for the current year, will answer your requirements perfectly.

YORK.—With your lens of the "rapid" type you certainly can take full-length *carte-de-visite* pictures, and very good ones too. You will have to place the camera about fifteen feet from the sitter.

BOTANIST.—Without special permission you will not be allowed to take photographs of the different specimens in Kew Gardens. You will have no difficulty in obtaining the necessary permission, we imagine, by applying by letter to the Director.

A. W.—The process of making photographs on "ivorine," described by us a short time back, is not patented, notwithstanding what you may be told to the contrary. You may work the process without let or hindrance. The process *is* open to all.

NEMO.—Between the lenses of six inches focus there is, practically, but little to choose. We should not advise you to select one of shorter focus than this. The height of the camera-stand mentioned is, we believe, about three feet six inches when set up

NOVICE.—The weak, flat appearance of the little enamel appears to be due to the transparency not being made sufficiently intense in the first instance. In future make them denser and tone to a greater extent. Do not subject them to too high a temperature in the firing.

AJAX.—The pictures are moderately good for a beginner, but they are capable of improvement. The chief fault is that they are all under-exposed and over-developed. Try the same pictures again, under similar conditions of lighting, and give at least double the exposure. With more experience you will have no difficulty in producing better work.

SMOKER.—You may safely indulge in your "weed" when developing the plate after the day's work is done. When you experience fog in the plates you may rely upon it that it does not proceed from the fumes of your tobacco. You must, therefore, seek for another cause.

J. E. WILSON.—Had you adhered strictly to the formula given by Mr. W. K. Burton you would have produced a totally different plate. In departing from the formula you have involved yourself in difficulties. The chief ones arise from the use of an unsuitable gelatine, which is very prone to produce "pits." Try again, but this time work to the formula given by the author.

W. R. S.—We do not know the *multum-in-parvo* accessory you name, so cannot pass an opinion on its merits as a "property." As a rule, when one piece of apparatus can be transformed into so many distinct pieces of furniture, the articles they form are very unlike anything found outside a photographic studio. As you state that it was made in "the days of glass positives," we should say its market value is very small indeed.

POITEVIN MEMORIAL FUND.—Our clever "P. D." has been "at it again!" In acknowledging Mr. J. C. Cox's contribution to this fund last week, and quoting from Mr. Cox's letter, the "P. D." makes that gentleman say:—"To few men does photography owe more than to Poitevin, although a mere amateur. I cannot but add my mite," &c., &c. If our "P. D." would have left the full point where Mr. Cox placed it—after Poitevin—the sentence would have read sensibly. Fancy Poitevin "a mere amateur!"

A. WHEELER.—The "puckering up of the film" (as you term it) in your carbon transparencies is what is technically known as "reticulation." It is always more prevalent in hot weather than in cold. It may, however, generally be avoided by drying the tissue more slowly, so that it occupies about the same time that it does in winter. You will find it a good plan to coat the tissue with plain collodion after exposure, and allow it to dry before squeegeeing it down upon the stratum of insoluble gelatine. With these modifications in your working we have little doubt you will master your difficulties.

RECEIVED.—B. Falk; Oscar Schölzig; A. Pringle; Dr. Nicol. In our next.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, on Wednesday next, July 2nd, the subject for discussion will be—*On the Best Method of Making Stereo. Transparencies.* The Saturday afternoon outing will be held at Teddington. Meeting afterwards at the Clarence Hotel, near the Railway Station.

ROBBERY OF LENSES FROM THE WOODBURYTYPE COMPANY.—At the Brentford Police Court, on Wednesday, the 18th inst., before General Sir Charles Daubeney, K.C.B., and General Tremenheere, Richard Carter, 1, Baynham-terrace, Ealing Dean, was charged with stealing, between the 3rd and 16th instant, three lenses and two mirrors, value together £70, the property of George Coope Whitfield, one of the principals of the Woodburytype Company, at Kent Gardens, Ealing.—Mr. T. W. Fry stated that he was manager to the Woodburytype Company, and the prisoner had been in their employment as operator's assistant for about nine months. The lenses and reversing mirrors produced were the property of the Company. On the 16th inst. there was occasion to use one of the lenses, and the prisoner was sent for it to the store-room. It was part of his duty to take them back to the store-room after use. He came to the witness and asked him for them, but witness replied that the prisoner was the last person who had handled them. He gave information to the police. The value of one of the articles produced was to the firm 60 guineas; the whole were valued at about £70.—Detective Constable Cluney deposed that at the prisoner's lodgings at Ealing Dean he found three pawn-tickets in the prisoner's coat. They referred to the lenses, and had been pawned for £3 6s. He went to the prisoner and showed him the tickets, when he admitted that he stole the property.—Walter Tattle, assistant to Mr. Harvey, pawnbroker, of Paddington, stated that the prisoner came and offered the large lens in pawn for 16s. Witness questioned him as to the ownership, and the prisoner replied that it was his own. Witness asked him if he wanted more on it, and he replied that he did not, as he only wanted the money for a short time.—Frederick Lear, assistant to Mr. William Ayres, pawnbroker, of King-street, Hammersmith, stated that on the 30th of May the second mirror was pawned at his place for £2, he believed by the prisoner.—Henry Finch, assistant to Mr. Clears, at 27, Goldhawk-road, stated that the prisoner pledged the small lens for 10s.—The prisoner, who asked no questions of the witnesses, pleaded guilty, and wished the case settled at once.—General Daubeney remarked that the persons who took in such valuable articles as the first two lenses should have made further inquiries as to the ownership of the articles, and they would probably lose their money. The prisoner would be sentenced to six months' hard labour.—The witness Lear stepped into the box and said that, so far from believing that the article was very valuable, he refused to lend the prisoner £3 on it as he asked, and he considered that the prosecutors might have taken better care of their property by having their names and addresses engraved on them.—*Middlesex County Times.*

JOURNAL OF PHOTOGRAPHY.

No. 1261. Vol. XXXI.—JULY 4, 1884.

KEEPING COOL.

The recent sultry weather has, no doubt, proved trying to most people, but to none more than to photographers, and plenty of opportunity has been afforded for the exercise of inventive genius in the direction of keeping cool. With the temperature standing, as it has done, over 80° in the shade out of doors, and probably many degrees higher in the more confined atmosphere of the skylight and dark room, it is readily conceivable that the ordinary photographer's resources must have been strained to the utmost; while, for those whose round of duties includes plate-coating, the time must have been a particularly trying one.

The mere storage of chemicals during such weather as we have lately enjoyed becomes a matter of no little trouble where the natural facilities of the establishment are, perhaps, never at any time of the best. Collodion, ether, alcohol, negative varnish, ammonia, and other liquids have an awkward way of taking matters into their own hands by either bursting their bottles or blowing out corks or stoppers at unexpected times, and thus causing, in addition to the waste of material, much danger and actual discomfort in the already unbearable atmosphere of the laboratory. Where this latter is situate in the basement little trouble will be experienced; but when, as in most cases, it is on the top floor, and exposed to all the sun's heat, some special precautions will be absolutely needful.

We have recently been watching with interest the variations in temperature in a basement apartment temporarily converted to photographic purposes, and have been astonished at the very slight fluctuations. A self-registering thermometer has shown a minimum of 55° and a maximum of 56·5° (with the exception of a sudden rise to 60° on one occasion) as the result of a month's observations, and this during a period when, in the skylight, the temperature has been over 100°. Where, therefore, a basement is available it is to be recommended; and for special purposes it is even worth the trouble to make a temporary change during specially hot weather.

When, however, a cellar is not available the best must be made of existing circumstances. So far as concerns the storage of chemicals, these should be placed as far as possible beyond the reach of the sun's rays, and preferably in a dark cupboard. With specially-volatile liquids, such as those we have already named, extra precautions should be taken to keep them cool. A simple plan we have recently seen in operation struck us as being particularly effective. It consists in wrapping the bottles in blotting-paper and standing them in a flat dish containing water. The blotting-paper envelope is thus kept saturated, and the evaporation which goes on keeps the contents of the bottle in a state of comfortable coolness.

In the same establishment we met with a device for preventing as far as possible evaporation of ammonia in the developing-room. An ordinary flower-pot of porous earthenware is filled with Calais sand thoroughly saturated with water, and into this the ammonia bottle is plunged up to the neck. When a dropping-tube is used no further arrangement is necessary, and it would not be difficult to devise means of adapting the same principle when it is required to use the bottle for pouring purposes.

We will conclude with one more "dodge"—this time for cooling and ventilating a plate-coating room. The lower part of the sash having been thrown up, the space is filled up with a frame in which are stretched, half-an-inch apart, three or four "sponge cloths"—a coarse, wide-meshed cotton material well known in the laboratory for dusting purposes. The sponge cloths are allowed to dip into a trough of water, by which they are kept saturated, and the air in passing through is simultaneously cooled and freed from dust. This plan, of course, involves the existence of means of keeping up a current of air.

PREPARING TRANSPARENCIES FOR COLOURING.

While sitting one day beside one of our ablest transparency painters, watching him at work, he referred to the impossibility of executing creditable work upon such photographs as he very frequently received for that purpose. It seemed impossible, in his estimation, to induce photographers to distinguish between the treatment required for a photograph that has to be coloured and one which is not to be subjected to artistic treatment of this nature. "Who," he inquired, "can do justice to skies so dark and 'grumly' as to render it difficult sometimes to read a piece of printed matter through them?"

We suggested the desirability of his subjecting each picture of this class to chemical treatment so as to be reduced previous to passing it over to the painters, several of whom were at the time pursuing their avocations. To this end we thought that a denuding ink possessing three grades of power might be made use of with great effect. The first, if applied to any particular part by means of a camel's-hair brush, should possess the property of dissolving the image entirely away wherever it touched, leaving the glass quite bare; the second should be able, when applied in like manner, to thin the image in a very material degree, but without removing it altogether; while the third should possess a property similar to the second, but in a much less potent form. "Could such inks be invented," said our friend the painter, "they would prove a great boon; but," added he, "most of the transparencies sent for painting, especially those on collodion, are varnished, and will resist the solvent action of the inks you suggest." To this we made response that the removal of varnish was really a very slight matter, as it would not involve any difficulty.

There are so many solvents of silver that a difficulty in making a selection meets one at the outset. For many years we have made bare our skies and removed objectionable features from transparencies, previous to their being coloured, by the agency of iodine dissolved in an aqueous solution of cyanide of potassium. When a strong solution has been prepared, and sufficient gum arabic added to impart a body similar to writing ink, it forms a denudent of great value.

Let us suppose that a dirty sky has to be removed from a landscape. The transparency is placed on the painting or retouching desk, the foreground to the top, and a brush charged with the destroying ink is run across the sky close to the horizon. There is no danger to be apprehended of its spreading inwards upon the film where it is not required, as the gum prevents this from occurring. By employing a larger brush the whole of the sky is treated in like manner, and it is now seen to be denuded of everything savouring of deposited silver. At this stage we usually prefer to wash off the solvent before proceeding further. When the film has become once more dry it will be found that by having laid the sky bare the horizon, which may be assumed to consist of trees or hills, will be found to be too heavy and lacking in aërial perspective. To lighten this a solution similar to the former, but much weaker and containing a larger proportion of cyanide, is applied to all the parts that are to be made retiring, carrying the solution down to the sky. During this operation a broad, soft brush saturated with water must be placed ready to be grasped and applied to the photograph the instant the reducing action is found to have proceeded far enough. It is scarcely necessary to say that the eye must not for a moment be taken off the part undergoing treatment.

Owing to the volatile nature of the agents in the reducing ink described, and also to their well-known poisonous properties, we have of late discarded them in favour of others more innocuous. Of these, ferridcyanide of potassium appears to be the best and most convenient to use. If a strong solution of this salt be applied to a transparency (or negative) by means of a brush the image instantly disappears. This property is very useful for employment under such circumstances as the entire clearing away of "skies" or "seas" which are to be afterwards painted in. Although every vestige of an image is removed a yellow, although transparent, stain results, to remove which it is only necessary that a solution of hyposulphite of soda be applied. By dissolving the soda salt with the ferridcyanide the action goes on simultaneously. When the soda is in excess the action is slower, and, therefore, more manageable; and when the solution is much diluted it may be rendered exceedingly slow. The ferridcyanide with which our experiments were made is a cheap commercial sample of the ordinary red prussiate of potash, which we find to answer so well as to leave no desire for any purer specimen—certainly it is so for the purpose in question.

What we suggest as the most practicable manner of utilising the solvent action of the ferridcyanide of potassium is to have two solutions—one saturated, or nearly so, which will act quickly and thoroughly; the other having its strength so much reduced by water as to remain on the transparency for nearly half-a-minute before its reducing action becomes apparent. Let the solutions be kept in small, wide-mouthed bottles, a brush to be specially reserved for each, care being taken throughout that each solution be applied by means of its own special brush. Two trays—one containing a solution of hyposulphite of soda, the other containing water only—must be placed beside the operator, who will proceed as follows:—The sky and all the portions to be made "bare glass" are subjected to the action of the strong solution, and the brush returned to that bottle. The weaker solution is then applied, first, to those parts which have to be most illuminated, such as the horizon, the distant hills and trees or other foliage, which are usually much too dark for effective colouring; and subsequently to other portions of the foreground which do not require much reduction. Expedition and judgment must be used, as the reducing action may proceed too far if delay be permitted. The instant everything is seen to be right plunge the plate into the tray of water and rinse off the ferridcyanide; then transfer to the hyposulphite solution, which in a few seconds will remove the yellowness, leaving the portions acted upon free from colour. Washing and re-varnishing follow.

We have referred to the facility with which varnish may be removed from a film protected by its agency. Make a solution of one part of caustic potash in ten parts of water, and add to this ten parts of alcohol. This solution, if applied to a varnished film, will dissolve the varnish, which must be removed by washing the film. This leaves the collodion surface in the state in which it was found previous to the application of the varnish.

SUPPLEMENTARY NOTES ON ALBUMENISED PAPER AND ALBUMENISING.

There are a few other matters in connection with this subject (which it was undesirable to embody in the purely manipulatory details) that it will be well to lay before those of our readers who may be induced to prepare their own paper. For instance: there is the vexed subject of blistering in the prints during the fixing and washing operations. It is true that many plans have from time to time been suggested for overcoming or avoiding this difficulty; but there is no question that, in the majority of cases, the evil has its origin in the paper itself, and also that it may be still further influenced for better or worse in the albumenising.

At the period when highly-salted and sensitised paper with far less gloss was in vogue, blisters were of rare occurrence. It was only when the extremely high glaze was introduced that the evil made its appearance in a really troublesome form, and it was then found that the higher the glaze of the paper the more prone it is to blister.

If we take a print which has blistered and carefully remove the blister, in most cases we shall find that it is not the albumen alone which has separated, but that a thin layer of the paper (or at least some of its fibres) has accompanied it, which clearly shows that the sizing material is not sufficiently adhesive to the body of the paper to withstand the apparent strain put upon it by the coagulated albumen during the fixing and washing of the prints.

Let us just see how the albumenising may influence the blistering. As we have said in our previous articles, if the highest gloss be desired the albumen must be kept as much as possible on the surface of the paper. Now, before the paper leaves the mill it is heavily rolled, and some albumenisers, we are informed, even roll the paper again before it is albumenised, so as to render its surface still harder and impenetrable. The paper is then floated on thick albumen, removed immediately it lies flat, and dried as rapidly as possible—artificial heat being used for the purpose. It is easy to conceive that with paper so treated the albumen does not penetrate beyond its outer surface. But if, on the contrary the paper be floated for a longer period, so that the albumen soaks more into it, and afterwards be allowed to dry slowly, we shall have the albumen more in the body of the paper instead of being confined to its surface only. When the paper is sensitised the nitrate of silver coagulates the albumen, and that which is in the body of the paper acts, as it were, the part of a supplementary sizing material. It is found in practice that paper which has been floated for a long time on the albumen, and then dried slowly—although it may have the same quantity of albumen upon and in it—rarely blisters; but such papers do not possess that high gloss which now appears to be a *sine quâ non* of a good albumenised paper.

Blisters, when the paper is very thickly coated, have been attributed to the silver solution not penetrating the albumen completely so as to coagulate it throughout, thus leaving the under surface—that next the paper—in a semi-soluble condition. This may possibly be the case in some instances; but it will not account for the albumen, as it usually does, bringing away the surface of the paper itself.

Some albumenisers we know attribute blisters to coating the paper while it is too new, and with them we are in a measure inclined to agree. Good paper, it is well known, like good wine, improves by keeping—doubtless because the sizing material becomes harder with age.

In connection with the age of paper we may mention a somewhat curious experience which occurred some few years back. A photographer purchased at a sale a quantity of albumenised paper at a ridiculously low price—only a few shillings per ream—intending to use it for parcelling purposes. However, a few sheets were tried for printing, by way of experiment, and it turned out, as was anticipated, quite worthless for photographic purposes. The paper was put away and forgotten for a year or more, when, being in trouble with his printing, it occurred to the owner that it might be worth while to again try this particular paper. This was done; it then proved all that could be desired, and was, eventually, used up to the last sheet. Clearly by keeping it had undergone some change, for its character appeared to be completely altered.

At the present time the fashion runs very much upon tinted papers. These are produced by colouring the albumen by the addition of one or other of the aniline dyes—according to the tint desired. The amount added must be determined by experiment. A little colour is added to the albumen—the quantity being noted—and a small piece of paper floated and dried. It is necessary that the paper be dried, as it is impossible to judge with accuracy of the tint while it is wet. Of course when once the quantity requisite is arrived at it will do for all time, bearing in mind that if the thickness of the albumen be increased the amount of colour must be reduced, otherwise the tint will be too strong by reason of the greater thickness of the coating.

In our previous articles—which were suggested by the frequent assertion that albumenised paper as of old could not now be procured commercially—we have given as full and complete working details of albumenising generally as it is possible to do in writing; but it must not be assumed, because the process is simple, that neither experience or judgment are required in the operations. Like every other process in connection with photography a certain amount of skill must be acquired before complete success is ensured, and albumenising paper is no exception to the rule. It is for this reason that we have recommended the beginner to commence by preparing the paper in quarter-sheets only. As a piece of further advice we suggest that, in all cases, if the exact character of the paper required can be purchased ready prepared, it will be to the advantage of the small consumer to buy it in preference to preparing it himself.

It is now pretty generally understood that highly-sensitised paper is likely to produce far more permanent prints than one that is only lightly sensitised; also, that a lightly-albumenised and strongly-salted paper conduces to purple and black tones as well as permanency. We cannot, therefore, avoid thinking that albumenisers would do well to supply paper of different kinds—such, for instance, as that at present supplied to be sensitised on a weak bath for those who require a high glaze and light-brown tones, and a more lightly-albumenised and heavier-salted paper suitable for a strong bath, for those who seek for purple or black tones and enhanced permanence. No doubt if a demand for such a paper as the latter really exists the supply will soon be forthcoming.

PHOTOGRAPHS AND THE POST-OFFICE.

When the *carte de visite* was first introduced into this country it took hold of the popular taste with such startling rapidity that, before two or three years had passed, many fortunes, we are within the mark in saying, were made by it. Its sway was long continued; the old glass picture became a thing of the past in first-class studios, and it was long before any change in its style was permissible. "Vignetted" busts almost from the first were produced, but that was all. Gradually, however, arose a feeling that the full-length portrait on the *carte* was too *petit* for the process of portraiture, and the half or three-quarter length in time almost superseded the long favoured style, till at last, in the shop windows—the great index of popular demand—the full-length *carte de visite* became extinct. The cabinet size was introduced in this country, but fell flat. It was taken to America, where it became very popular; went to the Continent and succeeded; and, finally, slowly crept into popularity in the land of its invention, until at last it shows every promise in first-class studios of entirely ousting the *carte de visite.*

We hear from every direction that this is so. The manufacturer, the dealer, and the photographer himself, all remark what a change is taking—or, rather, has taken—place in the popular demand. Some studios rarely take a *carte* picture at all now; and in others, where a general class of work is done, the cabinet pictures taken usually equal, if they do not surpass, in number the *cartes* taken. Thus, one gentleman informs us that two years ago he used to take about twenty *cartes* to one cabinet, while now he takes more cabinets than *cartes.* From another we learn that he looks upon *cartes* nowadays as an exception. Promenades, boudoirs, panels, and the numerous large sizes are more in demand in some quarters; but the staple work of the average number of photographers is the cabinet.

With this change in style a new and pressing consideration is involved which, from what we hear in almost all directions, is becoming most serious. We refer to the despatch through post of the many parcels which photographers make up and send to their clients, and which must be counted annually by tens of thousands. The packet of a dozen *cartes* and their wrappers, or even of a single *carte* with protecting boards, forms a compact little parcel which is easily handled and very slightly liable to get bent or broken through concussion or pressure. But with the cabinet the conditions are quite changed; with the increased area there is more risk of damage and less strength to resist it. The consequence is—what really might be expected—the packets of cabinet portraits get damaged in transit.

If a few instances only occurred it would simply be the annoyance of a few pictures injured, and no attention need be drawn to the matter. But the numbers so injured are not counted by single instances; they are almost universal; we should think there is scarcely a photographer in business who has not had sundry pictures irretrievably injured in the post — pictures that were packed in a manner to which apparently no exception could be taken. The professional photographer is thus injured in a twofold way. The growing demand for cabinets is, to some extent, restricted by those sitters who wish to send their pictures in the main by post having *cartes* in lieu of cabinets in many cases, to avoid injury in the post-office. We are sure our readers will bear us out in this assertion. Secondly, the number of pictures so injured is sufficiently large to constitute a real grievance between photographer and client; for we gather from our professional friends that it is looked upon as a matter of course for pictures so destroyed to be "restored"—practically replaced by fresh prints and mounts.

Having been greatly impressed by this state of affairs, we have made it our business to write to the Postmaster-General, pointing out the widespread nature of the damage inflicted, the serious loss which in many ways it entails upon photographers, and asking him for any suggestions in regard to the mode of despatching such parcels. An official has called upon us to discuss the matter, and we must confess it seems rather difficult to see any remedy. He points out that the damage will occur principally in certain districts, and is caused by the arrangement adopted by the Post-office for picking up and dropping letters. This is done while the mail is speeding along at its full rate. By means of automatic arrangements the train drops or picks up bags of letters at sundry stations along its route without in any way slackening its speed, and the consequence is that if the bag be a heavy one, or contain such parcels as cabinet pictures, they are bound to be crushed if they should happen to lie in an unfavourable position at the moment of contact with the wire netting which forms the receiving receptacle. Taking the rate at forty miles an hour, which is often exceeded, it will be seen that the picture would be dashed against the unyielding wire with far more force than if thrown from the hand with the greatest strength possible, and with increased danger on account of the miscellaneous crowd of letters, &c., all adding to the weight of the impact.

At present, therefore, we see no remedy but increased—greatly increased—strength of packing, which adds both to the expense of materials and the cost of postage. This will introduce an irritating question. Many, if not most, first-class photographers send their portraits out without charging for postage; but the increased charge which only, under existing arrangements, ensures safe delivery will form a very serious tax upon their cost, and questions of who is to pay the postage will arise and form fruitful sources of annoyance between photographer and client.

With a view of diminishing the cost of postage to the utmost exent we have suggested to the Postmaster-General that he should send us, or publish generally, a list of those places where the mechanical dropping arrangements are in force, so that photographers may put packing of increased strength upon all parcels sent in those directions. If such a list be forwarded to us we will give our readers the benefit of the information to guide them in their packing arrangements.

We may say that in the course of our conversation with the official in question we asked if sending parcels of cabinets by parcels post would not add to their safety; but he replied that he was afraid not, as the Post Office sends many parcels-post packages by the ordinary mail bags.

In conclusion: we may say that we consider the question we have opened to be one of very wide interest, affecting a far larger circle than that of the photographic fraternity alone, and our columns will be open for remarks upon the subject. Two very forcible questions arise — "Could not better arrangements be devised? Is it a proper thing that, as admitted, it is a matter of necessity that thousands of parcels be annually injured by the mode of working at present adopted?" In this age and in our country the present answer to be given seems a slur on our civilisation. Let the British public see to it, and memorialise the Postmaster-General.

In glancing over the paper, a copy of which has been sent to us, read by Dr. Hunter at the last meeting of the Edinburgh Photographic Society, we are led to inquire if it be not somewhat unusual for the essayists in the active Photographic Society of Modern Athens to give a species of negative confession of their own religious faith by pronouncing upon that of certain others. It has always been the custom in that and, indeed, in every other well-conducted photographic society to abstain from reference to party politics and sectarian peculiarities of religion. It is so in an emphatic sense in the conducting of this Journal; and, this being the case, we are precluded from publishing the paper in question. As it partakes rather of a Hindostanic than a photographic character the loss to our readers will be the less severe. We may say, however, that Dr. Hunter, without entering into formulæ or technical details, merely expresses his preference for the now nearly extinct waxed-paper negative process, which he considers, from its simplicity and relative cheapness, to hold out to artists advantages which modern processes do not possess. In the course of his paper he gave much interesting information concerning the temples and religious beliefs of India.

Prophesying, especially in weather matters, is proverbially unsafe. We have all heard of the old lady who took her weather glass to the door telling it, with something very like an expletive, to "believe its own eyes" as it stood firmly at "set fair" while a torrent of rain was falling outside. M. Montigny, however, has risked his reputation by prophesying that we, or at anyrate the people of Brussels, are to have a dry summer. In examining the colours of stars through his scintillometer he has noted that they display a predominance of green and violet, which he proves to indicate drought, while blue foreshadows rain. He explains the fact by supposing that water or ice in great thickness is blue, and that, as the stars in their twinkling do not show that colour, water is absent, and, therefore, a dry season is to be expected. We shall be better able at the end of the year to say if his prophecy be correct.

Our contemporary, *La Nature*, states that painters are finding a new use for photography. It says that when an enlargement upon canvas is desired an image is obtained in black lines which are most difficult of removal by covering with colour. Painters, when they wish to rub in a quick sketch, use charcoal, the lines made by it being readily removable. Nowadays, however, our contemporary says, all that is done is to take a negative and project an image on to the canvas, which is then outlined in charcoal by the painter. Thus, it goes on to observe, by allowing the artist freer play to his poetic fancies, photography so used is of great service to him.

This is, no doubt, very interesting reading for the public; but, seeing that details of such a mode of working were first given in our columns a dozen or two years ago, it is rather difficult to find the novelty of the plan now spoken of as though it were quite a recent invention.

Our readers may have noticed the reappearance of the corpuscular light again after a period of absence. *The Times* Berlin correspondent telegraphed a week or two ago to the effect that it had been seen there with a brilliancy equal to that observed in November. It is unfortunate that more photographic work in connection with it has not been done, the illustration in *La Nature*, alluded to by us some time ago, being the only satisfactory photograph brought before the public.

The reactions of albumen are always of interest to the photographer, and the body is of such a complex nature—its exact formula never having been agreed upon—that there is still scope for much information to be gathered. M. E. Grimaux, in *Comptes Rendus*, says that albumen in dilute solution behaves very differently from what is observed when undiluted. According to his paper, when one-per-cent. solutions are heated to 194° Fahr. for some minutes a few flocculi separate, but when the solution is then filtered it does not become turbid after being boiled. Carbonic acid in the cold gives a gelatinous precipitate, which redissolves in a current of air. The albumen is converted into a body having properties like the albumenates, closely bordering upon those of caseine.

The old joke of bringing home chips of the North Pole has given way to equally humorous suggestions for photographing it, and, as we know, some very interesting photographs have been taken of regions not far distant from that often-attempted goal. There is every prospect that before long pictures of regions still more closely adjacent may be obtained, for the Russian Admiralty are contemplating yet another expedition, with precautions suggested by the "Jeanette" disaster. The idea is to take an expedition a certain distance by steamer, and then by sledges and on foot. The party is to be divided into three sets, one going before the other and finding camping grounds and establishing depôts. It is estimated that it would take three years to reach the pole and get back to Siberia. It will be remembered what interesting and graphic accounts were given of the difficulties met with in one expedition, and how wet plates were frozen but yet gave good negatives. Fortunately, all that is done away with, and the gelatine plate will work with equal facility in cold as in more temperate climes, and much better than in tropical countries.

It is to be hoped that whatever make of plate be chosen for the outfit it will be seen that it is one with a thick, opaque film, so that no lack of delicacy may be brought about through back-reflection—a point which, as we lately showed, is of very considerable importance, and must be doubly so for views with such a preponderance of light objects as would be found in those icy regions.

We have frequently alluded to the Liverpool Astronomical Society, and the earnest work it has done. They have, in a pamphlet separate from their *Transactions*, just published a catalogue of five hundred stars in the constellations Auriga, Gemini, and Leo Minor, which have been determined from photographs taken with the equatorial stellar camera by the Rev. T. E. Espin at the Society's observatory.

GAS BOTTLES *VERSUS* BAGS.

I venture to enter a demurrer to what I understand to be the strong contention of the Editors that, on the ground of safety from accident, gas bags should be superseded by bottles of compressed gas for working the lantern. To ground presumed safety upon any such supposed "improvement" can only lead to calamitous results. There are various reasons for and against both bottles and bags; but in regard to the question of "safety," at present (in my opinion) the bottles are far more dangerous of the two, and even with the improvement spoken of they will not be more than equal in safety.

The great advantage of bottles is, of course, their portability and the saving of trouble. I have been glad, ere now, to get a bottle and carry it home myself rather than have the delay of the retort business, when time was precious and the light of a blow-through jet would suffice. But this only applies to large towns. If it came to travelling about, a lecturer would be subjected to very much uncertainty as to his bottles always reaching him in time, unless he kept a rather large number in use. On the other hand, with bags he can make his oxygen anywhere, and can fill up his other bag (even for a village) at the *last town* where they have gas, and take it on. And the expense also is rather seriously against the bottles. We can make eight feet of oxygen for a fraction under 1s. 6d., whereas in bottles it is charged from 5s. to 6s. 10d. To those who use the lime light constantly this would make a considerable difference, and it is on their behalf I question your sweeping conclusion.

In what does the presumed greater danger of bags consist? Using them with the oxygen underneath the pressure *must* be fairly equal, and any tendency towards mixture the uneven pressure is shown at once by snapping in the jet. No signs or contrivances *whatever* can or will prevent gross ignorance, or nervousness, or carelessness from producing explosive mixture by such causes as wrong connections. But this all applies equally to bottles; and there is no conceivable way of distinguishing a bottle which cannot be applied in exactly the same way to a bag.

On the other hand, in the varying pressure which has hitherto accompanied the compressed method there has been a most serious element of danger. This cause of mixture may elude even fair ordinary care, and I believe has eluded it in many cases, the strongest pressure running into the weakest, and so causing explosive compound. Be this as it may, and whatever the cause, in the United States, where bottles are used far more largely, explosions have been both more numerous and far more fatal than here. It is very rare for a bag explosion, even when it does occur, to cause loss of life; but the explosion of a bottle is like that of a boiler or a shell. Ask Mr. R. A. Proctor, who has lectured in the States, what *he* thinks of the comparative safety of bottles and of bags.

"Dust" as an alleged cause of bag explosion I believe to be a pure myth; at all events no explosion has ever been traced to that cause so far as I know. It is very easy to *purposely* produce a dust explosion in a bag; but it is quite another thing whether explosive dust ever has or can have naturally occurred in a gas bag, and one is not the slightest proof of the other.

The danger above pointed out will be removed by the improvement you mention, and that great improvement will also remove the greatest practical drawback and difficulty in the use of bottles. I have reason to believe that another inventor besides the one you probably refer to has about perfected a governor-valve for the same purpose. But if, as I understand you to suggest, this is accompanied by some simple apparatus for lecturers to do their own pumping with, we shall then be confronted with *another* danger of a very real character. In compressing gas a great deal of *heat* is produced—sufficient, in a familiar experiment, to ignite tinder in a tube by the mere sudden pressure of the hand. Now, *iron itself will burn in oxygen* if a particle of lighted carbon be brought into contact with it; hence the danger is readily seen, and I fear will be practically illustrated if we are to have people generally compressing their own gas.

In case I am thought an alarmist, it may be as well to state that, after a very serious explosion of a bottle some time ago at the Royal Institution (where, if anywhere, things should be well managed), the iron *was actually found burnt;* and it was supposed, or said to be, that it had been ignited owing to the heat produced by pressure. Granted that this risk would be diminished by the lower pressure you propose, it will still remain very appreciable.

I do not, however, question for a moment that the improvement you so warmly commend is worth all you say of it. It is; and will be one of the greatest boons possible to many—myself included—who are so located as to be able to take advantage of it. No one will be more thankful for it than myself. But bottles will still continue to have one special danger peculiar to them, and may also burst through flaw or want of strength at any time; and, on the other hand, I fail to see one single reason why bags should be considered inferior in point of safety. The same man who would "come to grief" with them might, if he acted in the same way, produce just the same results with a pair of bottles; and the same dangerous point (when pressure is almost all gone by exhaustion of gas) occurs in both alike. If there be any difference, my belief is that safety still lies rather on the side of the bags, even with the improvement in the bottles; without it, bags have the advantage by far. But, in either case, something like decent competence and care are the true and only preventives of accident.

I must say, finally, that an occasional accident from sheer carelessness hardly seems worth all the fuss made; and the general public, happily, do not seem so scared as one might think all of us were. Such accidents occur with house-gas, and candles, and matches, and suchlike; but no one dreams of abandoning their use, though we do try to keep young children and imbeciles from touching them. It is, no doubt, true that there are lanternists who do need to learn the necessity for *constant,* deliberate care with their apparatus; but, let us keep our heads cool, and, meantime, acknowledge our debt to those who, like Mr. Hardwich, are by calm experiment working their way to as *near* "safety" arrangments as the case admits of.

LEWIS WRIGHT.

PHOTOMICROGRAPHY AT THE HEALTH EXHIBITION.

THE increasing interest in the absorbing question of hygiene, as evidenced by the crowds attending the present Health Exhibition at South Kensington, induces us to say a few words, without too largely trespassing upon the domain of medicine, on the remarkable exhibits in the section devoted to the French department connected with the subject of bacteriology. Naturally, a subject which relates to the laws and media governing health belongs to medicine and surgery; but, at the same time, it is common public ground, in which all who value health may be considered to have a universal right. The more extended the knowledge of the construction and uses of such instruments as have been now brought together—being those which are actually employed by such *savants* as M. Pasteur, of the Normal School of Paris, and Dr. Miquel, of the Observatory at the Park of Montsouris—the more likely it is that others may be induced to profit by their researches, and lend help to one of the most difficult yet most interesting questions of the day.

Photographers are generally busy people, and too much occupied with the eye of the camera upon the "face divine," or on the lovely or rugged features of external nature, to be able to make a sacrifice in time—and we may be explicit, and say such study makes large demands; but many photographers are also wedded to the smaller observing eye of the microscope, and it is to these more particularly that our remarks may be acceptable.

The present phase of our knowledge of contagious and infectious diseases, through microscopic research, shows such rapid strides amongst the aërial germs that already such study has taken a fair position with those which are the subjects of strict scientific investigation; yet, without the necessary precautions against contamination, it would be liable to very erroneous interpretation, for we have to deal with the most minute and ubiquitous living organisms in the universe. To fully describe in detail all the beautifully-constructed apparatus exhibited would demand more space than can be accorded in these pages, and, moreover, the generally-appended tickets explain to a certain extent either the construction or the use, or both, of the special apparatus.

In dealing with this subject, the order of procedure will be inverted by alluding firstly to the exhibit of Dr. Miquel, which embraces various apparatus of considerable originality. This gentleman—the author of *Les Organismes Vivants de l'Atmosphère*—for many years has devoted himself to the study of aërial bacteriology, and to him we owe the present state of the statistics in this department of hygiene. He has taken up the subject at the point that was left by Drs. Maddox and Cunningham, and with modifications of the apparatus of the former and the adaptation of an aspirator, he has converted their qualitative examinations of the air into a quantitative analysis, upon which he bases the results of his most extensive series of experiments. For many years, and by various observers, an attempt was made to analyse the dust matter floating in the atmosphere; but the methods employed were faulty in many ways, especially as, being without any attempt at culture, it would be impossible to say whether such organisms as were mixed with the ordinary air-borne inorganic particles were living or dead.

Dr. Maddox employed a vane which consisted of a kind of multiple funnel for the passage of the wind, and which supported in front of the point of the receiving funnel a thin ordinary microscope cover glass smeared with a sticky, sterilised material, the cover, with its deposited dust, after certain hours of exposure, being removed and placed on a culture-cell for prolonged microscopic observation. The results of an extended series of examinations were duly published in the monthly *Journal* of the Royal Microscopical Society. Dr. D. Douglas Cunningham carried the observations still further in India, and published a thin folio with many figures of the principal deposits as found in the air of prisons and sewers.

Both of the methods used could only deal with the qualitative aspect; hence Dr. Miquel not only modified the aëroscope of Maddox so that it might be constantly in service, but, by adding an air meter and aspirator, he verified the amount of air transmitted, and was thus led by degrees to perfecting the apparatus exhibited. He has now several registering aëroscopes and also a kind of steam injector, by which a constant current of steam can be blown through a tube and induce a strong current of air by aspiration in its course, thus leading to the passage, if required, of 12,000 litres of air through the aëroscope per hour. The large injector can be attached to several aëroscopes, or to sterilised bulb-flasks, sealed at their points, containing sterilised, nutrient fluids—as neutralised beef broth—so that the moment the point is nipped off by sterilised pliers and the injector set in action, the air begins to pass through the liquid, leaving its air-borne particles in the fluid—a couple of sterilised asbestos plugs being placed at the opposite end in the tube fixed to the aspirator, to prevent the influx of aërial germs when detached.

The experiment, which may last any reasonable time, being finished, the fine point is closed by the blowpipe, the bulb removed, and set in the culture-oven. By using a large number of bulbs containing fluid from the same sterilised stock, carrying the experiment over a number of hours, each bulb having received a definite quantity of air, and by noting later on how many of the bulbs in the culture-oven have "gone bad" or show cloudiness, he infers the amount of bacteria in the air at that particular period and particular place. Some germs rejuvenesce in less than forty-eight hours; others may need several days. Some rejuvenesce earlier or later in liquids of a particular density rather than in the same fluid of higher or lower specific gravity, so that the bulbs are kept at a constant temperature in the culture-oven for a sufficient number of days to determine that the clear ones remain without change.

Thus, if from yesterday's experiment 100 bulbs "went bad" out of 500, and today out of the same number of bulbs 200 "went bad," then the natural inference is drawn that in the same quantity of air today there are double the number of aërial germs. The actual number of bacteria or fungi (mildew germs) is not required; for to count such would be practically most fatiguing and unnecessary, though this has been done several times by Dr. Miquel and his assistants, when the germs were deposited on a glass slide and retained by a sticky substance.

But the inquiry does not cease here; for tables are constructed showing the curves of temperature, rainfall, force and direction of wind, moisture, and number of bacteria at the same hours of the entire experiment. We are aware that Dr. Miquel has now pending some researches confirming a hitherto unknown condition of the atmosphere as regards the maxima and minima of the bacteria in the air at certain hours of the day and night. There is also a portable form of injector which is used for mountain experiments; though in the first essays of M. Frendenreich, conducted for Dr. Miquel amongst the snow-clad mountains of Switzerland, a pump throwing a litre of air per stroke was used, the results being forwarded, with all due precaution against contamination, to Dr. Miquel for cultivation and comparison.

Still Dr. Miquel has not rested here. He has obtained the assistance of Commander Moreau and Dr. Plantymausion, of the Mediterranean service, and through their aid, using various forms of apparatus, he has been enabled to analyse the sea air, both near and far from the land. The interesting results are published in the *Semaine Médicale*, 6th March of this year, and the researches show the purity of sea and mountain air. At different points in the city of Paris, also in the sewers, experiments have been conducted at the same time and similarly to those at Montsouris, and thus a general idea is gathered of the aërial dust in very different places and conditions.

This article will be completed next week, when we will deal with the other parts of the exhibit, also M. Pasteur's, and with the photographic aspect of the subject.

TRANSATLANTIC JOTTINGS.

At a meeting of the Photographic Section of the American Institute a very cogent proof of the value of photography was given by a correspondent of Frank Leslie's *Illustrated Weekly*. Photography has almost destroyed the business of the miniature painter, and where his work was only mediocre, or worse, has improved him off the face of the earth, and the gentleman in question (Mr. McSpedon) faintly indicates a similar fate for the "special artist." This artist and correspondent, who has had a wide experience, says most of his sketches on his recent tour in the far West were made with the assistance of photography. Whenever he halted he went directly to the photographer, and through him gained the best and readiest means by which to illustrate his descriptions. He was convinced, he said, that the travelling artist or correspondent hereafter would have very little to do with the making of sketches. Voyages round the world have ere now been written from an arm-chair in Fleet-street; but the idea of the possibility of "our special artist" receiving his inspirations from a source no further from home than from a bundle of *cartes* on his studio table is a terrible picture to contemplate.

The discussion initiated by Mr. W. E. Debenham's interesting communication on the subject of the *Illumination of the Dark Room* is carried on with a lively interest in America, many writers testifying to the value of the yellow-green screens for dark-room windows in lieu of the old ruby. The remark of one writer is worthy of quotation on account of its attempt at describing a colour without reference to the spectrum scale which, there is no doubt, is "caviare to the general." This writer, treating only of gas-flame illumination, places at six inches from the gas-burner a screen of *olive-green* glass and two thicknesses of *lemon-yellow* tissue paper. The special tint of the olive-green he describes as being, when looked through, "that peculiar, rich, greenish-yellow so common in this latitude, in summer, in grass and foliage just at that moment when the sun has set and the sky is cloudless."

The editor of the *Photographic Times* (New York) describes a method he has employed, in several cases, with success for reducing the prominence of objects forming a background to that portion of a picture in which it is intended that the chief interest should centre. By means of the burning of materials, which produced a dense smoke at the back of the object to be delineated, he was able to fog the background, as it were, and throw up the desired object with any amount of force, in a manner far superior to the effect obtainable by stopping-out the background. Such an expedient should be very useful in the photographing of machinery, as a jet of steam might very easily be sent in any direction, and from the pure white colour it presents it would impress the plate in an instant before contrary currents of air sent it in the wrong direction.

Mr. H. J. Newton (whose soda developer has often been alluded to in these pages) gave at the Section above named an exact formula for quick work, which runs as follows:—

Carbonate of soda	15 grains,
Carbonate of potash	15 „
Sulphite of soda	15 „
Water	1 ounce,

and pyro. two and a-half grains to the ounce. He also adheres to his mercuric accelerator, and said he seldom found anyone to fail when following his directions. The iodide of potassium used in making the solution should be largely in excess, and the failure to make the solution in this manner will account for a large number of failures, he believes. We give this precautionary advice of Mr. Newton's for what it is worth. It is, however, difficult to imagine how the verdict of English experts who have examined it and pronounced against it can be reversed.

The very small quantity of sulphite given in the above formula is not likely to do much in the way of keeping the negatives free from yellowness. Its other functions, recently dealt with at length in these pages, would not be perceptible with so small a quantity. It is, however, difficult to account for the remarkable proportions of the ingredients in some developers published on the other side of the Atlantic. So much so is this the case that we are tempted to believe the formulæ mere blinds to hide knowledge considered more valuable.

Mr. Roche gives a formula for what he terms a "combination alkaline developer," which, he says, is "equivalent to all the alkaline developers put into one bottle." We do not think he is far wrong, and we should advise a few developers less to be put into the bottle; for, when we reckon up his proportions, we find that for every grain of pyro., in addition to two minims of ammonia (a very large allowance), he adds five grains of carbonate of potash, over three of carbonate of soda, sulphite of soda less than a grain, and bromide the twelfth part of a grain. A formula like this is almost sufficient to fog a piece of leather, though Mr. Roche states that dry plates would not fog in it nor become stained!

A method of making an aqueous shellac varnish, based on one first published in our pages by Mr. G. Watmough Webster, was given by Mr. Gardner at this Section. As it would be rather useful for some purposes we here give the method in Mr. Gardner's words:—He "took boiling water fifteen ounces, and to this added two ounces of aqua-ammonia, and two ounces of white shellac dissolved in three ounces of alcohol." We think the formula would be greatly improved by adding the ammonia to the spirituous solution of lac and then the boiling water as in the first-named case; otherwise there would be a violent disengagement of gas before the lac could be acted upon.

Mr. Edward L. Wilson has a droll disquisition on the connection between a photographer's prices and the state of his health; yet it contains some truths on the state of the photographic business. Speaking of the cheap man, he says:—"Working in a fret, as he does every day, hunger pressing upon him continually, he never has time to think of anything but his stomach, and so lets all the other good things of this world go by." * * * "Art journals, photographic books, &c." "Why do Rocher, &c., &c., get better prices than others? Because they feed well intellectually and physically, and, therefore, have more of Rocher, &c., to put in their work."

A correspondent of the *Photographic Times* (New York) gives a method of removing the albumen film from a sheet of paper that if successful may turn out to have a considerable sphere of usefulness.

The plan simply consists in soaking the print in a saturated solution of borax, when the film becomes loosened and may be stripped off. We have not yet tried the plan, though we may do so, as there are many instances where a stripped film would be very valuable.

EXPERIENCES ON THE THAMES.*

From Abingdon there is not much that is interesting until we come to Culham, about two miles lower down—the river flowing the whole way through fertile meadows and banks covered with wild flowers and forget-me-nots, whilst further in the stream in shady, secluded spots we pass by many banks of pure white water lilies.

Passing through the lock we reached the junction of the weir stream with the river proper. We thought it would be a good idea to try to ascend the weir stream and see what the mill was "like" (for the mills are usually picturesque). We found it extremely hard work rowing against this rapid stream, and, needless to say, we had the water entirely to ourselves. The Philosopher thought it very much like ascending the Niagara below the Falls. I did not think it was quite so bad. At length, after a hard pull, and dodging the swiftest part of the stream as much as possible, we succeeded in getting pretty close to the mill, and in a most sequestered spot near the Pool we moored our boat to shore. Whilst the Philosopher had gone with the camera to get a good view of the mill from above I made the first use of all our elaborate cooking apparatus, which had hitherto lain idle. We decided upon making some tea. The spirit lamp, of course, came into requisition, and unfortunately caused an accident that might have been serious. All was going on well between the kettle and spirit, when all at once I tilted the boat on one side, which overturned the kettle containing nearly boiling water, and the lamp full of spirit, causing the flaming spirit to flow in all directions. However, by the use of our rugs, I easily managed to extinguish the flames and put an end to what at first appeared to be a rather alarming state of things. Not to be done, I made a second and successful experiment at tea brewing, and this time without *contretemps*. The Philosopher never slept a wink that night, and on finding out next morning it required a handful of tea to make two cups he thought he knew the reason why, and decided he would never again have his nerves upset by tea of my manufacture.

From Culham we had hard work to get our "man o' war" along. The wind was diametrically opposite to the direction we wished it to be. It was now blowing quite a gale and the river became covered with white-crested waves—"breakers" the Philosopher called them—causing our boat to dance up and down as if we were on the sea, and sometimes we even shipped water. Finding we made very little headway we again resorted to towing. This change, however, in our means of progression was the cause of a very serious accident to one of our cameras; for, whilst towing the boat round a rather difficult bend, the towing line got entangled in the tall reeds, the boat gave a lurch, and the coxwain, to save himself, fell upon one of the rigged-up cameras by his side, causing a collapse of that valuable piece of apparatus. As no immediate remedy was at hand we packed the damaged camera away and waited until we arrived at Clifton Hampden to see what could be done.

Passing under the railway arch at Appleford we next came in view of the quiet village of Long Whittenham, where supposed Roman earthworks have been discovered and some fine Anglo-Saxon jewels exhumed.

Another short pull brought us to Clifton Hampden—an extremely-picturesque place, even including its inns. First we thought of staying at the "Barley Mow" on the right bank; we made an inspection and came to the conclusion that it was a very curious place. We then had a look at the "Plough" (the alternative), also a very curious, thatched, old-fashioned (and that is saying very little) place. We thought this was one of the earliest species of inn ever invented. We decided on trying the "Plough," and had not the slightest reason to complain. The only difficulty was (although the inn is so small as to possess only two or three spare rooms) that of finding our way upstairs, the staircase being nearly vertical, perfectly dark, and about eighteen inches wide. Our host of the "Plough" and all his had contracted habits in harmony with their tranquil surroundings, for we found 10 p.m. was their curfew hour (excepting the night we were there), whilst they are up between 5 and 6 a.m.

Our first thought, after having satisfied our somewhat wolfish propensities incurred by towing, rowing, and photographing, was to try to heal the wound caused to the camera. The Philosopher, who is ever ready on an emergency, and besides deeply learned in the physical and chemical properties of gelatine, at once thought of his favourite medium. But the good people of Clifton Hampden scarcely knew of the existence of this "desiccated extract of the ossiferous portions of defunct animals" (the Philosopher's own definition), and we failed in our efforts to obtain any. We next suggested there might be a carpenter in the place, and for a consideration there would be a means of either begging, borrowing, or stealing his glue-pot. At last, after some trouble, we got an introduction to this worthy man, who, on finding out what was the matter, suggested he could do the work better himself. We thought differently, and by means of a bribe obtained possession of the much-coveted pot. The Philosopher, who adds to his many accomplishments that of being a skilful mechanic, made a very neat mend. We hung it up to dry that night and next morning were glad to find it could again be pressed into service.

Rarely have we found any village so picturesque as Clifton Hampden, and rarely one so well ordered and neat. Almost every few yards we found something we thought a worthy subject for the camera. Our inn was as rural and quaint as could possibly be imagined, and we photographed it with two or three village children as an appropriate foreground. The church there is situated on the brow of a hill overhanging the river—

"Which, hid by beech and pine,
Like an eagle's nest, hangs on the crest
Of purple Apennine."

A prettier church or one more charmingly situated it would be difficult to conceive. It is a most attractive and graceful object (and for the camera too) as seen from the river, and will bear the closest inspection, for externally and internally it is about perfect. From the tower of the church we may obtain, at this high elevation, a fine view of Oxford, and of the silvery meandering streak, up and down, of Father Thames passing on his way to the ocean—

"The tranquil cot, the restless mill,
The lonely hamlet calm and still;
The village spire, the busy town,
The shelving bank, the rising down;
The fisher's punt, the peasant's home;
The woodland seat, the regal dome—
In quick succession rise to charm
The mind, with virtuous feelings warm;
Till where thy widening current glides
To mingle with the turbid tides,
Thy spacious breast displays unfurl'd
The ensigns of th' assembled world!"

Perhaps one of our most successful pictures at Clifton was that of the bridge, with the church steeple behind. To adorn a rather tame foreground one of us posed as the "complete," though unsuccessful, "angler." At first, if we ever had nothing to do, we used to get out our line and try to hook a fish or two. Neither of us are really piscatorially inclined; however, we did not wish to go up the river without such a usual accessory, so before starting we purchased rod and line. We were told we were going in for the "'something' at one end and a worm at the other." But we paid no heed to such base insinuations; we intended to show results. We read Isaak Walton's advice—"When you fish for roach or dace you must have a small hook, a quick eye, and a nimble hand." About the former there can be no doubt, for we have placed that *small* hook under a glass case; with regard to the latter we thought that between us we had a "quick eye" and a "nimble hand." However, we never caught anything, but were afterwards told by a man at one of the ferries that many people came and remained whole days without catching anything. "Extremely interesting occupation!" we remarked. After that we never were again the "something at one end," but for posing purposes frequently used the extended rod without line at all.

The village school at Clifton is another pretty "bit," but it becomes almost invidious to point out one or two when every cottage and every gateway seems made subservient to art-rules. We learnt the reason, however: the Squire owns the village, and is, or used to be, the Vicar besides; consequently he allows Clifton Hampden to be none other than a model village. We left Clifton with many regrets, and wondered whether we should

"Look upon *its* like again."

There are many easier ways to see and enjoy the beauties of the Thames, but we doubt if there be any which possesses so many advantages and attractions as that of rowing down the river in a small boat. There is no hurry, no race for coach or train, and it was, indeed, on one or two occasions, in the absence of a head wind, pleasant work quietly gliding down the tranquil stream, and admiring those lovely scenes around us—such scenes of which the poet speaks:—

"Everywhere
Nature is lovely: on the mountain height,
Or where the embosom'd glen displays
Secure sublimity, or where around
The undulating surface gently slopes
With mingled hill and valley—everywhere
Nature is lovely. Even in scenes like these,
When not a hillock breaks the unvaried plain,
The eye may find new charms that seeks delight."

After passing Clifton Hampden the hills, capped with clumps of towering trees, become very picturesque and assume a somewhat bolder character. We next passed Little Wittenham church nestling in a luxuriance of foliage, and then the river makes a circuit with low and fertile meads on either side—at this time heavy with a rich crop of hay being gathered in. Farther on we come to the River Thame, whereon, a short distance up the stream, Dorchester is situated. We regretted

* Continued from page 377.

we could not spare time to row up this interesting tributary to see that ancient "city" with its remains of Roman Amphitheatre and half-ruined abbey, and which now, like many another "grand old city," has long since descended to the grade of a poor village.

A short pull from the junction of the two rivers brought us to Shillingford, where we made some "shots" at the bridge, several of which were during heavy showers, which considerably "damped" our enthusiasm, and had the unfortunate effect of somewhat hastening our return to London. However, we obtained very fair results in spite of the rain, although we were by this time getting rather disgusted with the "Clerk of the Weather," and on leaving Shillingford we were not in the most cheerful mood, with water everywhere around us. Shillingford is another "antiquated old place," as books tell us. However, we failed to find anything of interest in the place, except the "Swan" Inn, duly patronised by us, and which is certainly about the most picturesque on the river, being literally covered with roses and other flowers.

(To be continued in our next.)

ABOUT PRINTING.

The revolution which, a few years ago, so rapidly deposed wet collodion in favour of the now almost universal gelatino-bromide seems to have concentrated the thinking and experimenting powers of the great body of amateur photographers on the production of the negative, which is merely the means to an end, to the exclusion, in particular, of the print, which is the end itself.

This fact was forcibly pressed on my attention by the observations of a friend—one of the most successful amateurs on this side of the Tweed —during a conversation on matters photographic a few days since. Pointing to a number of prints which looked fairly good in the absence of contrast with the best that the negatives were capable of giving, he said :—"I am really disheartened with the result of my efforts to produce good prints, and more than half inclined to give it up as a bad job. I don't think I shall ever exhibit a print again, or at least one of my own printing." The friend in question is not far short of being *facile princeps* of northern amateurs, and his collection of prints has been much admired by all who have seen them, including, I may add, himself, until very recently, when an incident occurred which revealed the fact that they were not nearly so good as they might have been.

It seems he had been showing some prints at a gathering of friends, when one of them—a clever professional photographer—requested to be permitted to borrow several of the negatives for the purpose of producing prints for his private collection, and when he returned them showed the owner of the negatives the prints he had secured. To say that the professional printer had produced better prints than the amateur conveys no idea of the actual fact. They were so much better, and so very different, that nothing short of actual knowledge would have convinced even an expert that they were printed from the same negatives. They were delightful in tone, brilliant, juicy, and different in form and arrangement. Squares had been made into ovals, oblongs turned to uprights, foregrounds increased or curtailed; and in one case where in the amateur's print the mast of a vessel reached quite to the top, in that of the professional it was surmounted by a charming sky with delicate cloud effects.

Now, although I do not say that all, or perhaps even the majority, of professional photographers are such clever printers as the one here mentioned, it is well known that, in the larger establishments at least, the printing is superintended by an operator whose whole time is devoted to it, and the amateur who enters into competition with work so produced is indeed heavily handicapped.

Should the amateur, then, either employ a professional printer when he wishes to see his pictures at their best on the exhibition walls, or content himself by privately showing to admiring friends such work as he can do himself? By no means. He has shown that he can hold his own in the production of negatives; and if he would only devote a little of the time and attention to the theory and practice of printing that he has given to them, I have no hesitation in saying that his work would soon compare favourably with the best artistic productions usually seen in our exhibitions.

The art of printing has been far too much neglected by amateurs—looked upon as merely a mechanical process, to be taken up at odd times when there was nothing else to do, and when negatives had accumulated to the extent of a dozen or two. If he sensitise his own paper, the bath, probably dirty and of uncertain strength, is hurriedly filtered, and the sensitising is carried on simultaneously with several other occupations, the result being that no two sheets are left in contact with the solution for the same length of time, and are consequently not amenable to the same treatment. If he use paper ready sensitised his stock has been on hand long enough to have undergone a change, or he procures a fresh supply that may be very different from anything he has before employed, and the single print from each negative that he requires is printed before he has made himself acquainted with its peculiarities, or ascertained the best method of obtaining good results on this sample of paper.

I have said "a single print from each negative," and wish to direct particular attention to this as one great cause of weakness in amateur printing. Negatives, like almost all other things, have each a special character of their own, requiring peculiar and sometimes very different treatment. Two that may to the untrained eye look precisely alike will, with the same treatment, yield results altogether dissimilar; while each with treatment suited to its character will give perfect prints. No doubt the trained eye constantly engaged in printing operations will know at once, in the majority of cases, how exactly to manage each separate negative; but the amateur, who prints only by fits and starts, must feel his way, and can only make the best work by a system of trial and error, which implies the making of several prints from each of his batch of negatives.

An examination of the collections of most amateurs, or even of their pictures in our exhibitions, recals also the fact that they are very unwilling to sacrifice any portion of what they consider a fine negative; and hence we see otherwise fine pictures spoiled by excessive foregrounds or objectionable marginal objects left to retain the full size and proportions of the plate, and which, if the pruning knife had been freely and judiciously applied, would have been gems of both pictorial and technical excellence.

I suppose there is no finality in the production of negatives; and, therefore, while not advising amateurs to "rest and be thankful" always with what they already can accomplish, I would urge them to rest in the meantime, and till they have mastered the difficulties incident to the production of prints as perfect as their negatives, each keeping before him the fact that the best negative in his possession is but labour in vain, so far as he is concerned, as long as he cannot produce from it an equally good print. But he will never succeed in doing this while he looks upon printing as a merely mechanical operation. He must learn to feel that it is one requiring both knowledge and skill; must regard each negative as a wise parent does each of his children, and try to ascertain its particular character and idiosyncrasy, not considering several sheets of paper wasted in the attempt to discover how best to make it yield the most perfect result. Neither should he encourage a hankering after the full size or shape of the negative, but must ruthlessly cut off a foreground that dwarfs the principal objects in the picture, or mask the sky so as to add to its height, and lop off the sides so as to convert an oblong into an upright, if thereby a better result be secured. In fact, he must consider the negative in all its bearings, not as a thing of beauty *per se*, but as a means of enabling him by thought, care, and skill to produce an artistic picture.

John Nicol, Ph.D.

WHERE TO GO WITH THE CAMERA.

[It is hoped that this series of articles will be continued at regular and frequent intervals during the vacation months, and we shall be glad to receive contributions to the series from any friends able to treat of new and interesting ground.]

A TRIP AMONG THE ENGLISH LAKES.

In the hope that the spell of good weather, which broke over the north about the last week of May this year, might continue for a week or two, I set about preparing myself and my "touring kit" for a long-anticipated trip among the English lakes. Although I may not be able to offer anything but "stale news" to many readers of this Journal —though my trip was suddenly cut short prematurely by family matters and what looked like a set-in of bad weather, and, besides, nothing very startling or very instructive occurred during my little trip—still, at times, a little light reading is beneficial to our general public, and I offer to the Editors a few notes on my ten days' experience among some very grand scenery.

I am happy to think that the days are far past when the production of negatives was a matter not only of great bodily toil but of difficult operation and doubtful issue at the best. We do not now scale Yosemite precipices with tons of baggage, nor even crawl through the country with uncanny-looking vans. We throw our camera over our shoulders, or carry it in our hand; nor need we "groan and sweat" under a tropical tent. We can put our prepared plates in a case or even in our pocket, expose them, and develope them at home with a cup of coffee or a lemon-squash as ready to our hand as our sulpho-pyrogallol. All this has given a great impetus to amateur photography; my only wonder is that the impetus has not been greater. As a matter of expedition the sketcher is not "in it" with us, while a man who can both draw and make a decent negative is a man to be admired and envied. Our science has now reached such a state, and our manufacturers have attained such perfection, that any person of ordinary intelligence can, with a little practice, make himself pretty certain at any time and under almost any circumstances of getting, if not a perfect picture, at least a fair and pleasing transcript of whatever he offers to his plate through the medium of his lens.

To attain the "consummation devoutly to be wished," what is the trouble requisite? A trifle—a mere nothing! Supposing the tourist to buy his plates packed, he requires nothing but a ruby or other non-actinic lantern, some packing paper, and a little gummed paper, besides a pocket book, and who is without one? These articles are absolutely all that are required beyond the camera, stand, plates, and lens that are so useful in photography. (It may seem curious—even inexplicable—that without one or other of these articles I never yet produced a negative that I could well send to an exhibition, but so it is.) The above articles were all I carried about with me, and the lantern I might have done without had I cared to ask photographers in Keswick and elsewhere for the use of their dark rooms.

As usual, like a fool, I could not content myself with one camera. I took my largest (a 10 × 8), and for instantaneous work I took also a smaller one—the same that went round the world with me. I not only carried changing-boxes for these cameras but also slides. I might have saved the trouble of one or other. I further took two pairs of strong legs; my wife usually carried one set, the other set carried me! My camera legs were "quite too utterly" heavy, but when once set up were certainly rigid enough and exceedingly adjustable, the worst thing being that I had to carry always a key or spanner for the nuts. I did *not* carry a sledge-hammer or a hydraulic press. The fact is I had somehow lost my ordinary stand; but I so liked the ease of adjustment for awkward places given by my heavy stand that I am trying to get a stand made on the same principle but of less weight, and not requiring a tool chest to be carried. This is a long story about my stand; but it is worthy of it, for it could be made nine or ten feet long—about one *storey* high, in fact. I decline to tell how many plates I took with me, but I brought home thirty-four exposed plates.

On the evening of May 27th we arrived at Lodore Hotel, by the side of Derwentwater, in Cumberland, my slides and changing-boxes being all filled. Next morning, about 6.30, I went with my big camera a mile or two towards Borrowdale, and got a couple of very good views from a point a bit up a hill, climbing which I found that though I had come in a train I had not come in training; but I must not be *entrainé* into these silly puns! After breakfast I climbed partly up Lodore Fall and "let fly" at a couple of views; but, as I expected, the wind among the foliage spoiled the effect. My picture is truly a "moving scene." There was also very little water in the fall—about the size of a grey horse's tail, but not nearly so big as the Grey Mare's Tail, near St. Mary's Loch, in Selkirkshire. Then my little camera came into requisition, and I took a few dark "bits" in the bed of the stream below the fall.

The 29th brought to light a very beautiful view of Borrowdale and Castle Crag. I found the view, before breakfast as usual, behind a village called The Grange, about a mile and a "bittock" from Lodore. It was a beautiful calm "bit" of river with tall reeds growing, and three cows who would not stand still—the *low* beasts! However, their distance lent enchantment to my view, and their restlessness has not done much harm. If a cow has two digesting apparatuses why should she not have two heads and two tails?

That afternoon we had a drive round Derwentwater, but no particular event came of it. I took two small views with rapid exposure; visited Friar's Crag, and resolved to let the Friar alone till some other time at least. Next morning, having hired a trap to take us to Grasmere, we returned to the Crag, but I only secured a view of the boat landing at Keswick. I know that views of Friar's Crag sell well, but it was a "sell" to me, for I could make nothing of it. Resuming our journey *en voiture* towards Grasmere, we drove through Keswick up a steep hill, getting every here and there glorious views of Derwentwater and its adjacents. At one time we had a lovely panorama of Bassenthwaite Water, and at another we saw the beauties of the Vale of Newlands. I exposed two rapid plates on views of this grand sort, not expecting good photographs, but merely hoping to fix on my mind the outlines of the mountains; but my plates were covered with curious meandering, crapey markings, which looked so detestable that I threw the plates away unprinted. This is a kind of mark that I have occasionally noticed before; it comes always in distant hills or sky. Will anyone explain the matter to me? Driving along the Vale of Naddle we got a good view backwards along the Vale of St. John, and at last, after passing the queerest ecclesiastical building in Britain—I dare not call it a church—we arrived on Dunmail Raise, whence we overlooked Grasmere lying in all its quiet beauty beneath us, with Helm Crag on our right—a hill sometimes called the "Lion and the Lamb." Both my wife and I saw the likeness distinctly, only it turned out that I was viewing the whole mountain, and she noticed only a big boulder at the top of it. We were quite satisfied all the same.

Arriving at Grasmere, and having refreshed, we set out view-hunting. Carrying the big camera we "prepared to mount," but after a long walk we turned back viewless. However, on nearing our hotel on our way back, I got two pretty views of Grasmere and Helm Crag; only one view has a gas house and a gas-holder for a foreground, and the other seems over-exposed, though printable.

On May 30th I began with a couple of views of Grasmere from a wood near the hotel, and then, catching sight of some particularly good photographs in a shop window I proceeded to inquire where the artist lived. I found he was Mr. T. A. Green, a native and inhabitant of the village, and to his abode I proceeded, not only wishing to know the producer of such artistic work, but hoping to get leave to change and pack plates in his dark room. This facility was given me at once and cordially, and I had the privilege of seeing some very fine work by Mr. Green, not to mention partaking of various cups of tea with Mrs. Green. While "fossacking" about Mr. Green's place I came upon one or two exceedingly ingenious affairs—a very good wash-trough for prints, a very useful system for joining several prints from several negatives, a first-rate stand for carrying printing-frames, but, neatest of all, an arrangement for carrying a big camera along a bad road, or even up the "fells" of that district. I tried to persuade Mr. Green to give your readers the benefit of this vehicle, but his modesty seemed to stand in his way—or, rather, in *your* way. I hope he will relent and let us have a description and drawing. The thing looked like a cross between a bicycle and a plough. It had a wheel in front and long curved handles like a plough, and the camera case sat about the centre of gravity. Considering that Mr. Green takes a 15 × 12 Rouch's camera up some of the highest mountains it will be believed that some such contrivance is required. I found the convenience of a proper dark room for packing plates, and, having a small bottle of sulpho. pyro. and some ammonia and bromide, I developed a couple of plates and found all going well as regards exposure. Every tourist, I think, ought to develope a plate now and again when he gets the chance. Not only is it a check as to exposure, but his camera or slides may have sprung a leak, which without this precaution would remain undetected and the whole tour lost.

Our best day was the 31st of May, and a glorious day it was. My wife and I drove early to the foot of Rydalmere—not to the *bottom* of the lake, as some have it. We began with a bridge over the Rothay, in a darkish situation. It is a good enough footbridge built on rough piers of stone, but I could not quite get the whole bridge in, which does not look very well. I carry only one lens for each camera. For my 10 × 8 I use a rapid rectilinear—a cracked one, by the way. I am sure that people make more mistakes by using a host of different lenses and plates than in any other way. For some reason I cannot state I do not like views taken with wide-angle lenses, and when any one lens does not suit my view entirely I simply pack up and "shunt."

At the foot of Rydalmere I got several lovely views which have been depicted by painters and photographers without number. On a calm day, when the reeds are steady, some of these Rydal views are as well adapted for our work as any I know. This same morning—before breakfast, I omitted to say—we rowed across Grasmere and got a view of the "Wyke Cottage," once the residence of the Barbara Lewthwaite of whom Wordsworth sang. All this time the weather had been lowering in the evenings, and everyone felt sure that bad times were coming; but the rain kept off as long as it could apparently. Grasmere is to Derwentwater what Maggiore is to Como. Derwent and Como are perhaps grander, the hill lines more imposing, and the sheet of water more extensive in appearance (of course Lago Maggiore is larger than Como really); but for peaceful scenery commend me to Grasmere and Rydal, as also to the parts of Maggiore about Baveno and Pallanza. I do not wonder at poets making their homes among the quiet Westmoreland lake scenery.

On Monday we did but little, there being too many tourists about; but on Tuesday, June 3rd, we took a drive up Langdale, Mr. Green being in our company as *cicerone*. The Pass and Pikes of Langdale are very imposing, but there was a nasty haze on the hills which rather made me fear for the results of my work. However, on the way up the valley I got four or five views which at least repay the trouble of taking them and carrying the camera a mile or two. Though we knew there was almost no water in Dungeon Ghyll we determined to climb to it, and a fine climb we had on a very close, warm day. Having tired myself very much climbing a steep gully we found that we were on the wrong road altogether, for we had climbed Stickle Ghyll in place of Dungeon Ghyll. However, having carried my camera for miles at 103° in the shade in California, I was not to be beaten. So we retraced our steps, and finally, exhausted, we reached Dungeon Ghyll—an ugly-looking fissure in a rock, with a mere driblet of water flowing through it. The wind, too, had risen as ours fell; but I had a "shot" at the Ghyll in spite of the wind moving the ferns and shrubs, and the result is pretty fair.

On our return to Grasmere I found the whole sky dark with curious-looking, square and pyramidal objects. The passages of the hotel were also lined with these strange objects, and at first I attributed them to some novel kind of meteoric shower; but on closer examination I found them to be cameras and stands. A few gross of the members of the Amateur Field Club had turned up at the hotel. I was so amazed that I have lost count of dates and numbers: for my wife says it was on the Wednesday and that there were only six gentlemen, and no doubt she was right. I had on the Wednesday a "crack" with one of these gentlemen, and I found he had been getting some good views, making a lot of drop-shutter exposures. I am not fond of such quick work for landscapes, but with the wind that prevailed it was the only way to do.

We drove to Ambleside in the afternoon. I took one view of the old mill, and went to bed hoping that the weather next day might be better than it promised at night. Rising early on Thursday morning I found a steady, determined downpour of rain, and, as it looked like lasting, we started for home by the first train we could get from Windermere.

I had thirty-four negatives 10 × 8 to develope, besides a few smaller ones; and having now got them done I have to report a very fair average. My exposures have all been about correct, and in some cases the distant hills have been preserved with sufficient clearness; but the great majority of my plates are spoilt with insensitive lines about half-an-inch wide and an inch from the edge of the plate. This necessitates my cutting down my prints, which in most cases sadly mars my intended compositions. This is the more exasperating because the quality of emulsion is first-class. In spite of the nuisance of coating and drying gelatine plates I shall have to recommence the process if I cannot get good emulsion, *well laid on,* in the market.

If I secured nothing else I gained a considerable amount of exercise and health, and I can recommend a tour to the Lakes to anyone who is dyspeptic or out of sorts. Travellers, however, must have their pockets full of money, for the hotels are very dear. With all my experience of hotels I do not think I ever got less for my money than at some of the hotels by the Lakes. The charges depend more upon "season" than upon reason. ANDREW PRINGLE.

THE ROYAL INSTITUTION.

MONSIEUR E. MASCART ON COLOURS.

It is a bold undertaking to address you in a foreign tongue on a subject which is not new to you, and in a theatre in which you are accustomed to hear the greatest minds expound their discoveries. You will find, without doubt, that it is legitimate on my part to ask all your indulgence, under the desire that my honoured friends shall not have to regret the invitation they have done me the honour to give me.

THE SPECTRUM.

Light is characterised by two qualities—its intensity and its colour. The comparison of two lights having the same colour can be made without having recourse to our organs of sense and by physical means; but it is impossible to compare different colours without the intervention of the physiological impression. It has been known since the time of the labours of Newton that white light—or, to be more precise, the light of the sun—is formed of a great number of different colours, and that the union of all these colours in the same proportion, acting upon the eye either simultaneously or in short intervals, reproduces exactly the impression of white.

Starting with the preconceived idea of an analogy to the notes of the gamut, Newton divided the solar spectrum—that is to say, the image obtained by decomposing white light by means of a refracting prism—into seven different colours. In reality this division is arbitrary, the colours passing the one into the other by insensible gradation, and each of them being characterised by their refraction in a prism, or, rather, by the length of the undulations to which they correspond.

When we reunite at one point a portion of the rays of the spectrum, we obtain either one of the primitive colours, more or less pure, or a new tint. If we arbitrarily divide the spectrum into two parts, and reunite the rays of the separated parts, we obtain two distinct colours, the superposition of which again reproduces white light. This can be proved experimentally by means of the ordinary spectrum, and it is effected naturally in the phenomena of rotary polarisation, by which the most brilliant colours are obtained.

VISUAL LUMINOUS IMPRESSIONS.

These general properties are stated only in order to deduce two conclusions. It should be noticed that the mixture of pure or homogeneous lights in any proportion whatever produces always on the eye a single impression—that of a single colour. Whilst the ear can distinguish all the notes which constitute harmony the eye seizes but upon one colour, without the power of distinguishing if it be really simple or formed of different lights. In the second place, the mixture of colours provokes but one new impression. That of purple, for instance, can be obtained by mixing red and violet, and all the varieties of rose colour are nothing but mixtures of purple and white.

White light can be reproduced by two simple colours only, such as red and green. In a more general manner, if three carefully-selected colours of the spectrum be isolated—such as certain shades of red, green, and violet—it is possible, by mixing them in different proportions, to imitate the impressions produced by all colours. Artificial colours, formed by rays taken from the spectrum, for example, may be either simple or composite, without the eye being able to distinguish between them—except, perhaps, when they have a shade of purple or rose, because these two colours are known not to exist in a simple state.

It is the same whether the colours be those of nature or those artificially manufactured. An object appears coloured because it returns to us a portion only of the light which it receives from the general supply. The separation may be made by transmission, as in coloured glasses; or by reflection, as by metals; or by diffraction, as by the wings of certain butterflies; and by the coronas which are sometimes seen around the moon. The portion of the light which does not reach the eye is absorbed, or sent off in a different direction. By studying the phenomena of fluorescence it will be seen that an object has not colour in itself; it can but utilise from the general supply of light the tints which are proper to it, and the aspect which it presents is very different according to its mode of lighting. A red riband, for example, placed successively in the different colours of the spectrum appears black, except in the red portion of the spectrum; it then returns by reflection an almost homogeneous light. A rose-coloured riband appears to be illuminated in a very unequal manner in various parts of the spectrum; the light which it reflects is, therefore, very complex.

THE PHENOMENA PRESENTED BY MONOCHROMATIC LIGHTS.

It might be asked, what would be the effect in nature if the light of the sun were absolutely homogeneous. Certain bodies would absorb it completely, and appear black; others would reflect it more or less actively, and they would exhibit more or less luminous intensity. If no other standard of comparison existed the eye would give the sensation but of white, black, and intermediate shades. It does not appear to be necessary to give any proof; but an experiment is never useless, and it always serves to impress ideas.

Pascal said that nothing would cause the properties of air to be better understood than to be where it did not exist; in the same manner, nothing would better serve to make known the properties of colour than seeing the aspect of the world under the influence of homogeneous light. The volatilisation of a salt of soda in the flame of a Bunsen's burner realises this condition in a manner almost perfect.

With similar illumination fabrics of the richest colours appear but white, black, and shaded; the art of the painter exists no longer. Behold under this light a superb picture by Ed. W. Cooke, lent to me by Sir W. Bowman, and which represents the aspect of Venice under the setting sun. It seems nothing but an engraving. Here, again, see two landscapes painted under the influence of the sodium light by an artist who thought he was employing none but black and grey colours. He was using, in reality, the most brilliant colours, as you will see when you look upon the picture in ordinary light. This bouquet of flowers is nothing but a collection of white and grey blotches upon black foliage. The human figure assumes a cadaverous appearance. It is necessary to witness a spectacle like this several times over to completely appreciate all its features of sad and sepulchral monotony. Assuredly it would be a strange punishment to be obliged to live under these conditions; and we should be filled with joy indescribable if the wand of a fairy brought out in their ordinary colours the objects around us, as I do at this moment by lighting a strip of magnesium. I am sure that you yourselves feel a sort of relief at coming to the end of this lugubrious experiment.

COLOUR-BLINDNESS.

The recognition of colour being due to the impression produced on the retina, it is a foregone conclusion that the human eye will not always exercise this function with equal accuracy.

At the outset the different parts of the retina are unequally competent to indicate colour. To distinguish the details of an object it is necessary to direct the attention towards that object; that is to say, to produce an image on the central region of the retina, where the acuteness of physiological perception is much the strongest. It is the same in relation to colours. When the gaze is concentrated in a fixed direction, and a coloured object is placed in the visual field in such a manner that its image is produced laterally, it will be noticed that the perception of its colour becomes enfeebled more and more the farther it is removed from the line of central vision, and is lost towards the limits of the field.

But the most important fact is that different observers do not distinguish the various colours with equal facility, and they even confound with each other colours which appear to us to be the most discordant—such, for instance, as red and green. The discovery of this particular form of infirmity is due to Dalton, who was affected in this manner to a very high degree, and who analysed the errors of his judgment with the greatest care. We are in the habit of calling "Daltonism" that which you call "colour-blindness;" and that is, perhaps, abusing the name of a philosopher who has several other titles to have his name handed down to posterity. This defect of the eyesight, so long unperceived, is in reality very common. There are fully ten persons out of every hundred who in comparing colours commit errors sufficiently grave to give the power to put them in evidence for close examination. In general, this imperfection of sight is not inconveniently serious, and is unconsciously corrected by habit, the recollection of objects, and the judgment of others. The case, however, becomes extreme when they cannot distinguish, for example, red from green, a cherry or a ripe strawberry in the middle of foliage, a red light or a green light in railway signals or those used in navigation. Artists have often a marked predilection for certain colours. Lesueur put blue in profusion in all his works. Your great painter, Turner, appears to have sought more and more for red tones. There is reason, perhaps, to inquire whether the choice of colours by certain painters is absolutely intentional, or whether it is the consequence of a physiological state.

People are often colour-blind from birth, but this defect of sight is sometimes the result of an accident; in certain nervous affections it is manifested occasionally in a temporary manner and under the most bizarre forms.

COLOURS IN APPARENT RELIEF.

Vision is more liable than the other senses to numberless errors and illusions. To speak only of those which relate to colours the effects of the contrast of two adjacent colours may be cited, or those which follow the impression of an image, or, again, the subjective colours seen with closed eyes because of a mechanical action of the eye, and I will limit myself to bringing before you several experiments relating to the apparent relief of colours.

When we examine an image of the spectrum upon the screen, produced by a direct-vision prism, the various colours appear to be upon the same plane; but if we slowly turn either the diaphragm or the prism the illusion is presented of a wave in relief, of which the red extremity is in advance. The effect is more distinct when the slit of the diaphragm has the form of a V; the spectrum now appears to be a veritable cylinder. On replacing the diaphragm with another having the word "DAVY" upon it in transparent letters, we can see upon the screen, and with extreme exaggeration, the letters standing out in relief, as is sometimes the case with the names fixed over certain shops.

THE INVISIBLE RAYS OF THE SPECTRUM.

In addition to the colours which are seen habitually, the solar spectrum contains other radiations—the one set less refrangible than the red, and distinguished by calorific properties; the other set more refrangible than the violet, remarkable for its photographic effects and by the action which it exercises on fluorescent substances. The ultra-violet solar spectrum produced by the refraction of a prism extends almost to the same length beyond the visible spectrum as the length of that spectrum itself, and Mr. Stokes has demonstrated that the electric arc gives an ultra-violet spectrum five or six times longer.

It is astonishing that sight is restricted to so small a part of the radiations emitted by luminous sources. We may remark, however, that it is the same with the other senses. The touch will give no idea of the temperature of a body, except between very restricted limits; the ear perceives neither the deepest nor the most acute sounds, and the highest sound it can hear produces a painful impression. At the infra-red end of the spectrum the visible spectrum is arrested almost abruptly, and the efforts of Brewster but little increased the limit of the range of rays to be seen by the eye. It is only by ingenious processes—such as those which Captain Abney has employed with so much success—that we have obtained a complete history of this region.

On the other side of the spectrum the visibility persists in a remarkable manner. Helmholtz has discovered that, by taking the requisite precautions, it is possible to see the entire ultra-violet spectrum, so far as it has been revealed by photography. Having had occasion to study the light emitted by metallic vapours, I have proved and published that, with a prism of Iceland spar, ordinary eyesight can distinguish the ultra-violet spectrum to three or four times the length of the luminous spectrum. One of my *collaborateurs* with keener eyesight has seen and mapped all the rays it was possible for me to photograph. If, instead of considering the refraction of these rays, which varies with different substances, they are defined by wave-length or period of vibration, it may be said that the ordinary luminous spectrum is one octave in length, and that it is possible to see another octave more refracted.

In describing the different properties of light I wish here to interpose a few remarks. Sir W. Thomson has expressed surprise that Nature has forgotten to give us a special sense to enable us to see the magnetic phenomena in the middle of which we live. Here, on the contrary, we are in the presence of radiations which do not exist in the light of the sun—or, at least, which do not reach us—which are energetically absorbed by most transparent substances and in particular by the humours of the eye, rays of which we know absolutely nothing in ordinary life, and which nevertheless act upon the retina. The nervous couch of the retina is extremely sensitive to their action. Does it not seem that in this case we possess superfluous sensibility, and that there is a want of harmony in the structure of the organ and the uses it should perform?

A question arises in relation to this subject which is of great interest from a philosophical point of view, namely, whether man is susceptible of an organic perfection, and if it be possible to follow the line of progress marked by the seeing these colours, and consequently in the structure of the eye. One eminent Englishman has not disdained to occupy himself with this question. Mr. Gladstone has made a complete collection of the expressions employed by Homer to describe the colours of objects. It comes out clearly as the result that the terms of Homer are applied in a very uncertain manner, for the great poet seems to have confounded green with yellow and blue with black.

Before quitting the curious problem whether the sensation of colour is as yet but little developed, it may be remarked, perhaps, that the interval which separates us from Homer is a very insignificant one in the history of humanity; that the Greeks, but a short time after Homer, made great use of colours on their walls and painted statues, of which the specimens are so numerous that the frescoes of Pompeii present the most varied colours; and that even an attentive examination of modern authors tends to lead to the same conclusions as those which are drawn from the writings of Homer. In the middle of the seventeenth century, at the period in which Lesueur made a special use of blue in painting, is it not singular that a specially naturalistic poet, La Fontaine, never once employed the word "blue" to describe a coloured object or the colour of the sky? The smallest novel of to-day would furnish a collection of names of colours comparatively important. Literature has for its object the recording of the facts of history or the passions of man to produce the desired impression on the mind of the reader. The painter concerns himself alone with design and colour. For some time past—at least in France—it appears as if the parts had been interchanged: literature is becoming pictorial and painting impressional. Without recourse to a modification of our organs, the change of ideas and the desire to present something new suffices to explain the highly-coloured language of contemporaneous literary men.

Otherwise, if humanity is capable of such rapid development in the direction of perfection, it becomes necessary to admit that the people who have remained in the stone age, like the natives of Cape Horn, have not participated in the general progress. The French expedition, which remained for one year at Terra del Fuego, conceived the happy idea of studying the natives from this point of view. The language of the natives had names for only two colours—the one for red and analogous tints, the other for blue and green; but this poverty of language was due solely to the circumstance that colours do not play an important part in the existence of the Fuegians, since it was found that after a little practice they could distinguish and classify the colours and their different shades as accurately as the most civilised European. The organic development of their visual apparatus left nothing to be desired.

(To be concluded in our next.)

Producing Coloured Photographs.

This invention, by Albert Kepler,* Achille Morin de Premion, and Alfred Pigeau, received provisional protection only.

This invention has for its object improvements in the process and apparatus employed for producing coloured photographs, by means of which ordinary positives are rendered transparent, and consists in the employment of a certain solution or compound hereinafter described, by means of which and the aid of suitable apparatus, and in the employment of a wash for removing the surplus solution, the positives are made transparent and ready for being coloured at the back; after which, on applying suitable artists' oil colours on the back of the said positive, a most accurate and faithful representation of the objects in all their colours results—but which up to the present time by ordinary photography are only produced in black and white—by which means the cost of producing durable and brilliant coloured photographs is greatly reduced and simplified.

In carrying our invention into practical use or effect we take one or more ordinary photographic positive or positives and place the same in the preparer—which may be a metallic box, chamber, or receptacle so arranged as to admit of being adjusted to and maintained at a uniform temperature without any great variation or loss of the heat—in which preparer we have previously placed a suitable quantity of the solution or compound hereinafter described; this solution or compound is kept at a uniform temperature of 90° Cent.—say 195° Fahr.—which is maintained for three hours, during which time it is allowed to act on the positive or positives, and at the expiration of this time it is allowed to cool and coagulate and remain in that state for twelve hours. At the end of this time the preparer is again heated in order to allow of the withdrawal of the said positive or positives.

The solution, compound, or bath hereinbefore spoken of is composed of equal parts of clarified resin and essence or spirits of turpentine in about equal proportions, which are melted together and maintained at or in a liquid state or that due to a temperature of 85° to 90° Cent.—say 194° Fahr.—and this must be kept up whilst the positive or positives are in the bath for about twelve hours.

On removing them from the preparer they will be found to have a thick layer or coating of the solution or compound adhering to them, from which it is necessary they should be freed. For this purpose we employ a dryer consisting of a metallic trough or receptacle arranged with a jacket or casing into which steam, hot air, hot water, or other suitable and convenient means for heating—being adjusted to, and maintaining the required temperature—is or are allowed to pass so as to maintain the same temperature as that in the preparer, namely, 90° centigrade—say 195° Fahr.

The positives are placed at the bottom of the dryer—which is or may be provided with a false bottom and a ready and convenient means for removing the positives—and the heat causes the solution or compound to melt and run off from them to the bottom of the dryer; and when the solution or compound is fully liquid and has passed off the positives may be lifted out and suffered to drain for a few minutes without cooling, when the remaining solution or compound may be easily removed from the positive by the aid of a wash, consisting of benzine applied by the aid of a sponge or wad, or in any other convenient or suitable manner.

The positives are then laid on a perfectly-clean surface for a period of a few minutes till dry, varying according to the dryness and temperature, when they will be found ready to be painted at the back with the desired artists' oil colours, each of which is laid on uniformly over the surface it is intended to occupy without any regard to light or shade on such part; and in consequence of the materials used and the manner of employing the same, the paper on which the positive has been printed permits the colours to penetrate into and amalgamate with it in such a manner as to render them indelible whilst retaining the brilliancy and durability of oil paintings, and they may be then cemented or mounted on a suitable surface or surfaces and subjected to a strong pressure to render the adhesion complete.

By preference we employ the best artists' oil colours, which may be either those contained in tubes, or we may take the dry colours and mix them as required.

Our Editorial Table.

Double Albumenised, Ready-Sensitised Paper.

We have received from Mr. Otto Scholzig specimens of the different brands of ready-sensitised, albumenised paper. These are of two classes—"brilliant" and "enamel"—both being evidently more highly albumenised than the usual samples of foreign manufacture. On trial we have found these papers to give every satisfaction—printing rapidly, and toning easily by three or four of the most ordinarily employed formulæ. The toning formula issued with the paper consists of a combination of the acetate and carbonate baths; but we have found the plain acetate, the carbonate, and the borax formulæ to work equally well. With a leaning in the direction of brown shades, probably the phosphate would be preferable to any other bath. In spite of the strength of the albumen film we have experienced no difficulty in the matter of either blistering or cracking of the surface, and the film retains its brilliancy throughout the whole of the operations.

BURNT-IN ENAMELS. By R. T. WALL. LONGFLEET, POOLE.

WE have had submitted to us a specimen of photo-ceramic work executed by the process recently patented by Mr. R. T. Wall, in which the sensitive material employed is an extract of white pepper. This, upon exposure under a negative, forms an image in exactly the same manner as the ordinary "dusting-on" process; and, vitriable colours being employed, the image may be burnt-in in the usual manner. Without having tried the process we cannot speak of its capabilities; but, judging from the specimen before us, it appears well suited to the purpose to which it is applied.

HIGHLY-SALTED ALBUMENISED PAPER.

FROM Messrs. Rivot and Co. we have received samples of albumenised paper prepared according to the system of heavy salting advocated by us in the last and present issues of this Journal, and upon the advantages of which, as contrasted with light salting, we do not in this notice feel called upon to enter. When excited on a sixty-grain bath, as recommended by Messrs. Rivot and Co., it yields brilliant results. The particulars of salting and nature of the albumen employed were given by Messrs. Rivot and Co. in our correspondence columns of last week.

PHOTOGRAPHS. By B. J. FALK, New York.

SOME examples of a peculiar class of photographs are before us. Whether they can be considered as advancing the claims of photography to be considered an art is a matter of taste; but they, no doubt, exhibit evidence of cleverness in their production — a cleverness, however, which belongs rather to the stage carpenter than to the artist. The following account, taken from the New York *Dramatic News*, sufficiently describes them :—

"One of the most difficult feats in modern photography has recently been achieved by Falk, the Broadway photographer. It represents the heroine of the Curfew clinging to the tongue of the bell and swinging out over the town. The lady who consented to be the subject of this picture is the actress, Mrs. Charles Watson, and some idea of the discomforts she underwent while the photograph was being made may be gained from the following detailed account, which was procured from Falk by a representative of the *Dramatic News* :—The bell itself, which was specially constructed for the purposes of this picture, was of papier maché, and about three feet wide. As the object of the picture was to represent the heroine of the Curfew as she was being swung to and from the belfry tower, and as a papier maché bell is hardly substantial enough to support even the lightest form, the difficulties of picturing realism by artificial means loom up in all their staggering proportions. The bell having been made fast to the top of the skylight, was fixed at the proper angle by wires, which were so fine as to be invisible against the background. At the same a stout wire, painted such a shade as to lose itself in the colour of the background, was suspended from a brace in the centre of the skylight. This wire was attached to a belt which encircled the waist of the plucky heroine. By the aid of this central support she was enabled, while appearing to cling to the tongue of the bell, to reach the corresponding angle without any strain on the bell proper. The support for her hands was furnished by a stout rope which passed through the tongue of the bell. To obtain the proper effect a certain amount of realism was required, and it was intended that at the last moment the victim should really dangle in the air with no support under her feet. As, however, the slightest motion of the feet would have been detrimental to the picture it became necessary to attach wires to her heels, which wires, in the hands of an assistant, were to aid in raising and lowering the feet to the proper position. To add to the realistic effect it was desired to give to the dress and hair the floating tendency which under such conditions it is known to assume. As there were no blizzards or cyclones available for the purpose, this was effected by attaching numerous threads to an equal number of bunches of hair as well as to the trail of the dress. These appendages were operated by the mouth of the assistant, whose hands were employed in working the heel supports. When all preparations had been made the box on which the sitter, or rather swinger, stood was pulled from under her, and she was left to whatever support the central wire offered. This was a most dramatic situation. The agonised expression in the picture was more truth than fiction. There she hung waiting for release; every second seemed an eternity. A few feet away stood the photographer, calmly contemplating the helpless misery of his victim, yet, at the same time, closely watching for her swaying body to remain motionless for a second. It ceases to sway for an instant only, but this was enough to allow the light which had been concentrated upon it to do its rapid work. The signal is given and all hands rush to her support. She is cut down, a restorative in the form of wine is applied, and the agony is over. The severe strain upon the nerves of the brave heroine may be calculated when the reader is informed that it was only after the twelfth attempt that the final successful result was obtained, since in the other exposures there had been just sufficient motion of the body to destroy the sharpness of the picture."

As regards the technical qualities of the work it is needless to say that, as might be expected from Mr. Falk's establishment, it is beyond suspicion.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
July 8	Bolton Club	The Studio, Chancery-lane.
„ 9	Photographic Club	Anderton's Hotel, Fleet-street.
„ 10	London and Provincial	Masons' Hall, Basinghall-street.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society, held on the 26th ult., the chair was occupied by Mr. W. M. Ashman.

Mr. F. W. HART showed a case containing chemicals and appliances for developing quarter-plates, in the construction and arrangement of which economy of space had been especially studied and effectively accomplished. It consisted of a zinc box measuring six inches by four and a-half by three. This box when empty formed a washing trough, in which was a plate rack for holding the plates whilst washing, and by which they might be lifted out to drain. The case also contained two celluloid developing dishes, two zinc dishes, and a box containing chemicals.

Mr. J. BARKER inquired what was the proper way of using Schlippe's salt for intensifying negatives. With him it had stained the plate.

Mr. W. E. DEBENHAM said that it was necessary before using it to throughly wash out the mercury solution that preceded it. How long had Mr. Barker washed?

Mr. BARKER replied about ten minutes.

Mr. DEBENHAM said that half-an-hour was not too much. If the plate had been thickly coated with emulsion a longer time would be required.

Mr. A. MACKIE asked whether Mr. Debenham would explain what diffraction was. The subject had lately been introduced into the question of the use of lenses and stops.

Mr. DEBENHAM replied that when light passed the edge of an opaque substance a portion was turned very slightly out of its path and suffered diffraction. This portion was so small as to be quite insignificant compared with the whole volume of light passing through any but an extremely narrow aperture. As they had seen photographs taken with a pinhole aperture of $\frac{1}{150}$th of an inch, in which no effect of diffraction was visible, and that was much smaller than any diaphragm that photographers were likely to use, it was not likely to trouble them. A more probable danger was the reflection from the edge of the opening. When a hole of very small diameter was made in metal or card the hole really was apt to be a short tube, from the sides of which, compared with the amount of light directly transmitted, a considerable quantity of light would be reflected.

The CHAIRMAN observed that the subject of diffraction scarcely had a photographic bearing.

Mr. J. B. B. WELLINGTON showed a sample of gelatine, which when soaked in water displayed some curious markings. He inquired whether they indicated anything that would probably cause green fog. No very decided opinion was expressed by the members on the point.

This being the annual meeting, the Secretary then read his report, from which it appeared that the members had much cause for congratulation. It was noticed with satisfaction that the balance in the hands of the Treasurer showed an increase upon that in the last balance sheet, proving that the experiment of fixing the qualification at a low rate had been made upon a sound basis. The characteristic feature in the proceedings of the Association during the past year had been the series of monthly lectures, proposed and organised by the Curator, Mr. A. Haddon, and given by various members of the Association on subjects of photographic interest. Apart from these lectures many demonstrations had been given and articles exhibited, the discussions upon which had given rise to new theories, and instigated further experiments and investigations on subjects of photographic interest.

The acknowledgments of the Association were given for several donations, special mention being made of a volume on light and optics from Mr. J. Burgess; a blackboard and easel from Mr. J. H. Hare and Mr. Burgess; a changing and developing-box from Mr. W. E. Debenham; and copies of photographic publications regularly mailed by English and American publishers.

After a feeling allusion to the loss that the Association and the photographic community had sustained by the death of one of the members, Mr. H. Baden Pritchard, the circumstances were referred to that had prevented the late Secretary, Mr. C. B. Cutchey, from giving the full amount of time and attention to the affairs of the Society that he would have wished, and which eventually led to his resignation and the appointment of Mr. J. J. Briginshaw, the present Secretary. The increase in the funds and in the number of members introduced the expression of the hope that each recurring anniversary might witness a higher position won, and that the Association would find increased stability and a sure prospect of progress in usefulness.

REPORT OF THE CURATOR.

MY object in addressing you this evening is twofold—first, to thank those of our members who so kindly and willingly came forward in answer to my appeal to give us lectures on those subjects they were well acquainted with; and, second, to remind those members present this evening, and who may not have been present at all the lecturettes, what ground has been gone over by the lecturers.

The subjects dealt with in the lectures cover almost the whole of photography, in a general way. Mr. Darker showed us a series of beautiful experiments on light, mainly polarised, so as to give us an idea of the force with which we are constantly dealing; and a thorough acquaintance with which would, he considers, the better enable photographers to cope with the many difficulties they have every day to encounter.

Mr. Debenham told us what the lens attached to an ordinary camera obscura was when Daguerre first began to use it for photographic purposes, and how, step by step, it has been improved. The lens as used by Porta could only cover a plate f with a stop $\frac{f}{20}$ or $\frac{f}{30}$; by using a converging meniscus instead of a plano-convex a much greater area could be covered, other things being equal. He showed us a series of lenses from the very early attempts down to the most recent, and these, as most of you know, will now effect with $\frac{f}{5}$ almost as much as the original lens would with $\frac{f}{20}$ or $\frac{f}{30}$. In the course of the lecture it was remarked that opticians of the present day aim too much at microscopic definition at the centre, and neglect more than they should do the marginal definition. When they turn their minds to the improvement of this quality of the lens we may hope to see a great advance in the performance of the photographic lens.

Mr. J. Traill Taylor gave us a very interesting lecture on the manufacture of lenses, showing us what kind of tools are necessary for the production of the different curves on the surfaces of the glass, and the rough glass as received from the glass manufacturer; also the different grades of emery and putty powder used in the grinding and polishing of the glass to the curves determined upon by the mathematician. Mr. Taylor has done us a good turn by illustrating his lecture in the manner he did; but, unfortunately for him, I hope he will not stop there. Some four or five of the members of the Association are now learning from a practical man the *modus operandi* from beginning to end as regards the production of lenses. Will they stop there? I hope not. What I should, therefore, be glad to see would be the publication of a series of curves by means of which, with two lenses as a nucleus, one could lengthen or shorten the focus of such a combination, either by the addition of another lens or by the substitution of a lens of different focus for one of the two already in the mount, and, in addition, that all, or at least most, of the positive lenses could be used singly for landscape purposes. Mr. Taylor has partly promised to give us the necessary curves for doing what I have here pointed out, and I hope he will be as ready in redeeming this promise as he was his last to lecture on lenses.

Mr. W. K. Burton gave us two formulæ for the production of emulsion—one by the boiling method, and the other for very rapid plates produced by means of ammonia. The Ag Br produced by either of these methods can be allowed to subside, and then the supernatant liquid containing the altered gelatine and the salts resulting from the double decomposition poured off, so that perfectly-pure Ag Br is left behind. By "pure" I mean the sensitive salt freed from gelatine and foreign salts. Mr. Burton seems lately to have modified his formula very considerably as regards the quantity of gelatine associated with the Ag Br during boiling, and also the acidity of the liquid, in presence of which the ripening action goes on.

The next lecture should have been on the *Art Side of Photography: What to Select, What to Avoid, and the Reasons*; but, unfortunately, those acquainted with the subject are bashful and reserved, or do not care to enter upon ground which must be disputed at every inch. But, nevertheless, I hope this gap will be filled up during the next year.

Mr. W. M. Ashman told us of the different methods that are and have been adopted in order to prepare paper suitable for photographic purposes. He exhibited specimens of prints produced on paper sensitised on baths of different strengths, and showed also the great advantage gained in some cases by using ammonia gas before printing. Here, again, a link is wanting. This is a lecture *On Toning and Fixing*; but this, I think and hope, will be supplied by Mr. Ashman during the next season.

Mr. A. L. Henderson showed, as far as he possibly could in the time and under the circumstances, the method he adopts in order to produce his beautiful enamels, which are always so rich and full of detail, and, above all, as far as our present experience goes, permanent. The result obtained by Mr. Henderson during the lecture was quite sufficient to prove that he was the right man to call upon to give us a lecture on this subject, which by dint of hard work he has made entirely his own. This subject is so important that if photographers of the present day wish their work to be handed down to posterity they should take it up a little more seriously than it has been. I do not say that any one could go and produce right off an enamel such as Mr. Henderson is in the habit of producing; but with Mr. Henderson's lecture before him is he not in a better position than Mr. Henderson was when first he commenced work?

We cannot have too much of a good thing; so I for myself am glad that our Secretary has obtained the promise of a lecturette from Mr. Berryman on this same subject. Perhaps Mr. Henderson himself will be able to see an easier way of producing his enamels when he learns how others are working in order to produce like results.

Mr. T. Bolas gave us a most instructive and interesting lecture on the production of photographic pictures in fatty ink. He showed us how a Woodburytype relief could be used in order to produce a picture on ruled paper, so that the image could be transferred to zinc and stone, and then how the former could be used in order to produce prints at the same rate as letterpress.

Mr. W. Coles, during the last lecturette, showed us results and demonstrated on the spot how it is possible to alter the density of negatives which from force of circumstances have been produced either too dense or too weak. From what he told us I gathered that photographers ought always to try to get as much silver reduced as possible, and then, if necessary, to reduce the density by after treatment. When metallic silver only is left in the film there is less chance of after changes than when the silver is converted into some other form, the stability of which we know very little. When intensification is absolutely necessary, bichloride of mercury followed by Schlippe's salt seems to give a more permanent result than any other in the experience of the lecturer. Local reduction is most valuable, and in the hands of some can undoubtedly be made to improve negatives very much. For this purpose Mr. Coles prefers Mr. E. H. Farmer's reducer—ferricyanide of potassium and hypo.—in consequence of one solution only being required, so that as soon as the reduction is nearly completed the action can be arrested by washing.

The last chapter in this short history is in connection with Mr. F. W. Hart's lecture, wherein he gave us the exact dimension of furnace to be built, the proportion of carbonates and sand to be used with the haloid salt of silver to be reduced, and even the kind of fuel to be used in the furnace. The best precipitant for the silver from washings of prints Mr. Hart finds to be dilute H Cl, and from the hypo. ordinary sulphide of potassium; but in neither case should they be used in too large an excess, as the resulting compound of silver is slightly soluble in them, and, in addition, in the case of the sulphide, the smell to many is anything but pleasant. Mr. Hart told us that within his own experience he is able to recover about ninety per cent. of the metal employed, so that if photographers would only take heed of what he said they would be able in a very short time to diminish considerably the expenses in the printing department. A large amount of silver in many establishments, I am sure, goes down the sink, because the heads do not think it worth the trouble to save the hypo. for treatment. All photographers would not, most probably, care about reducing their own residues; but, fortunately, refiners are glad to do it for them at a small charge.

In conclusion: I beg once more to thank those gentlemen who so kindly gave us the lecturettes and responded so heartily to my appeal. One thing only I regret—that is, the small encouragement you have given to the lecturers. Nothing can, I conceive, be more disheartening to lecturers than to see only a small audience after the hours they have devoted to the preparation of their lectures. In future, therefore, if the experiment that has been made be continued, I hope to see a larger attendance; this will be the means not only of disseminating the useful knowledge imparted in the lectures, but, at the same time, of proving that the subjects of the lecturettes are of interest. The experiment is at an end. The result I leave to you to judge. If you think it a success, I will endeavour in the course of next year to lay before you an equally inviting *menu* and feast for the mind.

After the usual votes of thanks to the officers of the Association, the election of officers for the ensuing year was made, and resulted as follows:—*Trustees:* Mr. W. K. Burton and Mr. W. Cobb.—*Curator:* Mr. A. Haddon.—*Treasurer:* Mr. W. H. Prestwich.—*Secretary:* Mr. J. J. Briginshaw.

An alteration in Rule 7 was then, after some discussion, carried. The rule now stands as follows:—"The subscription shall be 5s. per annum, payable in advance in the first week in July. Each member on election shall pay the annual subscription, but from his second subscription shall be entitled to a rebate proportionate to the number of months that had elapsed during his first year before his election."

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE eighth meeting of the Session was held in 5, St. Andrew-square, on Wednesday evening, the 4th ult.,—Mr. W. Neilson presiding.

The minutes of the last meeting having been approved, Messrs. John K. Dawson, Alex. B. Dawson, and Richard Kerr Miller, C.E., were elected ordinary members.

A lengthy discussion took place on the new edition of the rules, proofs of which were submitted at last meeting by the Council. It having been agreed at that meeting to term them "laws," they were read *seriatim* and very fully discussed, Messrs. Forgan, A. B. Stewart, Forbes, and Craig Christie taking prominent parts. Some of the changes proposed were not adopted by the meeting. The laws of the Society and the order of business at its meetings were finally adopted as revised.

The CHAIRMAN intimated that he had made inquiries about the alteration of the municipal laws as to photographing in the public gardens of Edinburgh, and he found that no modification would be entertained, in consequence of the great nuisance that had arisen through excursionists having photographers among their number and bringing about a disorderly crowd.

Dr. ALEXANDER HUNTER read a paper *On the Waxed Paper or Calotype Process*, illustrated by upwards of ninety calotype prints, few being less than 12 × 15. These were examined with very great interest, and a cordial vote of thanks to Dr. Hunter was passed by acclamation. [Dr. Hunter's interesting paper dealing more with his Indian experiences than with practical photography, past or present, we merely refer to it briefly in another portion of our impression.]

Mr. NORMAN MACBETH, R.S.A., brought before the notice of the members the importance and desirability of making the study of the picturesque more an object of this Society, and for its encouragement in this direction handed for inspection the work which was awarded the first prize of the South London Photographic Society last year. That Society have instituted as one of their principal aims in their proceedings the setting apart each month the best production then submitted for competition—without names of parties concerned, but having a title or motto attached to each work. These again, at the close of the session, are submitted to a competent judge (unknown to the members, at least not having seen the works before), who adjudicates, and assigns the best. With a view to have a similar effort made in the Edinburgh Photographic Society he (Mr. Macbeth) tabled a resolution that it was his intention at the first ordinary meeting to move—"That we adopt such a proceeding, and appoint a small committee, who shall draw out the proposal in detail and regulate its management. This proposal to be afterwards submitted to the Council for their approval and recommendation."

Owing to the lateness of the hour several items had to be passed over.

The next meeting of the Society will be held on Wednesday, 1st October.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE monthly meeting of this Association was held on Thursday, the 26th instant,—Dr. Kenyon, President, in the chair.

The minutes of the May meeting were read and confirmed, and Messrs. Barker, Evans, Hartley, Hughes, and Moore were elected members of the Association.

The Rev. H. J. PALMER proposed, and Mr. A. W. BEER seconded, a resolution that the Shrewsbury excursion to Condover, Acton Burnell, Pitchford, and Buildwas Abbey take place on Thursday, July 17th, in lieu of the excursion to Churchtown, and this was carried unanimously.

The Rev. H. J. PALMER read a paper descriptive of a recent visit to Hawarden, and exhibited a number of specimens of his work there, including some fine portraits of the Premier.

Mr. R. CROWE described a number of exhibits sent by Mr. Atkinson, of Liverpool, including some bottles of corrugated metal for the safe carriage of concentrated developing solutions, Samuel's very ingenious changing-box slide, a camera fitted internally with Kirkby's shutter, and Blair's tourograph. The last exhibit excited much interest from its many novel and ingenious features. Mr. Crowe pointed out many of its advantages over other cameras, and especially its lightness and strength, the capital arrangement for the rising front and swing back, and the exceedingly clever double dark slide.

The CHAIRMAN announced the donation to the Society of fifteen 10 × 8 prints, by Mr. Beer; three numbers of *Photography*, from the editor in Chicago; and one number of the *Photographic Times*, from the editor.

Mr. H. SIMPSON described a cheap and compact camera and case combined, invented by himself. The case consists of a box of quarter-inch baywood covered with American cloth, and measures 12 × 7 × 10 outside. The side is hinged to the body of the case at the bottom. The camera bellows are fastened to the centre case. To use the camera, the side is unfastened and laid down at right angles to the case. The bellows and rising front are drawn out and kept perfectly rigid by wire supports, as used in the scenograph. These supports are strongly hinged one-quarter of an inch inside the case, and when closed up fold over the camera front. The side is hinged on the top, and a bag and frame (similar to that described on page 114 of the ALMANAC for 1881) is drawn out of the box. The bag is preferable to a bellows in this instance, as the former may be fastened within one inch of the edge of the case, thus leaving two inches of clear space inside between the end of the bag and the camera bellows. The frame is supported in the same way as the camera front. The plate is placed in an arrangement of metal gimbals held in position by brass screws and slides, thus giving the effect of a double-swing back. The gimbals are carried in a metal frame, which works in the two inches of space referred to, and is moved backwards and forwards by a rack-and-pinion motion. The pinion passes through the top of the inside of the camera, and through a packing-box at one end, where it is turned by means of a small stock key.

Messrs. Beer and Riley exhibited prints of negatives taken during the last excursion to Rivington Pike; Mr. Cornish some views in Devonshire; Mr. Plympton pictures in Hereford and Gloucester; and Mr. Crowe some instantaneous pictures taken with Kirkby's shutter.

After votes of thanks to the Rev. H. J. Palmer, Mr. Crowe, Mr. Simpson, and the other exhibitors, the meeting adjourned.

LEEDS PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held in the Philosophical Hall, on Thursday, the 5th ult.,—Mr. Washington Teasdale, F.R.M.S., in the chair. Messrs. Dawson and Hagyard were elected members.

Professor RUCKER, F.R.S., made some observations upon *Photographic Lenses*, of which the following is an abstract:—The ideal lens would so deflect the rays of light which fall upon it from any single point that, after passing through, they would meet in a second point which would thus form the image of the first. In real lenses this condition is not fulfilled, for two reasons. In the first place, convenience dictates that the surfaces of lenses must, in general, be either plane or spherical, and rays of light which diverge from a single point cannot, by passing through a lens bounded by such surfaces, be made to converge to a single point. Hence a defect arises which, since it depends on the spherical form of the surface of the lens, is called spherical aberration. In the second place, such ray of white light is broken up into its constituent colours, and to the separation of these is due (among other effects) that the position in which the best optical image is formed is not necessarily that in which the clearest photographic pictures will be obtained. [In the lecture the principal methods of diminishing these defects were briefly discussed.] Spherical aberration may be minimised for objects at a given distance by giving the lens a suitable form, but the connection will be less perfect for other distances. The distance from the lens at which the image is formed is also dependent on the distance of the objects. A lens in which this defect is marked fails to form a clear picture of objects which are not all at nearly the same distance from it. The blurring due to this is diminished by reducing the size of the pencils of light which pass through the lens by means of a stop. This, however, is attended with the disadvantage that the amount of light which falls on the plate is reduced, and therefore also the quickness of the lens is diminished. If the stop be placed close to the lens the rays which pass through it at different angles are brought to a focus at different distances, so that either the centre or the edges of the field are indistinct. In this case the field is said to want flatness. By moving the stop away from the lens, rays parallel to the axis pass through the centre, while those inclined to the axis are transmitted by parts nearer to the circumference of the lens. The fact that the focal length is different for the central and circumferential parts is thus utilised to diminish the curvature of the field. This remedy, however, tends to produce distorted pictures; but the nature of the distortion is different according to whether the stop is in front of or behind the lens. By placing it between two lenses, opposite distortions may be made to neutralise each other. The use of two widely-separated lenses is attended with the drawback that the quickness and angle are diminished. Finally: chromatic aberration, or the breaking up of white light into its constituent colours, has to be avoided; and this may be done by the use of compound lenses, the various parts of which are formed of different kinds of glass. The principal points referred to may be thus summed up:—A small stop increases the depth, but diminishes the quickness of the lens. Moving the stop from the lens diminishes the curvature of the field, but increases the distortion and reduces the field of view. By the use of two lenses, with a stop placed between them, the distortion may be diminished, though a great distance between the lenses reduces the field of view. A large aperture increases the quickness; a large focal length diminishes it—the time of exposure being inversely proportional to the square of the diameter of the opening, and directly proportional to the square of the focal length

The principles above enunciated were illustrated by the care of a combined objective for landscape and portrait work.

The CHAIRMAN, in opening the discussion, referred to several points mentioned by Professor Rucker, and illustrated the principles by facts from his own experience.

Mr. PEARSON said he had a shutter made by a well-known maker which worked between the lenses of a doublet, and consisted of two circles passing each other in the centre of the lens. According to Professor Rucker this varying aperture must be gradually cutting off the vertical rays in a vertical, but not in a horizontal, plane, and it would, therefore, appear that a shutter made on this principle must give a blurred image.

Messrs. Marshall, Warburton, Bramson, Reffitt, and Walker also joined in the discussion.

Mr. J. B. Spurge, of London, was introduced to the meeting by the Chairman, and very heartily received. He exhibited and gave a description of his sensitometer for testing gelatine plates.

Mr. Asquith exhibited an instantaneous shutter, simple in mechanism, but most effective for the purpose required.

The CHAIRMAN, on behalf of the Sciopticon Company, exhibited the new quarter-plate camera, Manx stand, and lenses for ditto. This camera was much admired on account of its extreme portability and the great range of focus it possessed.

The meeting was then adjourned.

NORTH STAFFORDSHIRE PHOTOGRAPHIC ASSOCIATION.

THE ordinary monthly meeting of this Society was held on Monday evening, the 30th ult., at the Mechanics' Institute, Hanley,—Mr. Charles Alfieri occupying the chair.

The minutes of the previous meeting having been read and confirmed, the Secretary presented his financial report for the past six months, showing a balance in hand of £1 7s. 9d. The report was adopted.

On the motion of Dr. Griffiths, an excursion was arranged for to-morrow (Saturday), the 5th inst., to Alton Towers and Croxton Abbey, the party to meet at Stoke-on-Trent, and proceed thence per rail to Alton.

The CHAIRMAN cautioned the more inexperienced of the members against over-exposing their plates. He last week found the light very actinic in the same district (Derbyshire), an exposure of one second having been too much in taking a view of Haddon Hall.

Mr. W. B. Allison passed round some fine platinotype prints from negatives of groups of ferns.

After some conversation upon various topics of photographic interest the meeting terminated.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

THE Association met on the 22nd May, when Dr. Kayser occupied the chair in the absence of Professor Vogel, who was attending a meeting of the Senate of the Technical High School.

The Chairman laid on the table the specifications of three patents, amongst which was Schlotterhoss's automatic printing arrangement.

Herr Pietschmann wrote to say that he wished to arrange for a photographic tour amongst the mountains this summer, and invited members of the Association to join him.

Herr Schultze showed a shutter to be placed behind the lens.

Herr Scamoni, of St. Petersburg, sent a number of photo-mechanical prints after well known pictures.

Herr QUIDDE called attention to some peculiar matt streaks on a few mounted cabinet pictures, which proved to be caused by small cracks in the surface of the paper, and which were not noticeable in the unmounted prints.

Herr JOOP thought the albumen with which the paper was coated was at fault, and recommended mounting the pictures before they had become quite dry, or, if for any reason it were inconvenient to do so, the pictures when taken out of the water might be roughly dried with blotting-paper and then placed between sheets of paper and rolled, albumenised side outwards.

Herr QUIDDE called attention to the gold, silver, and bronze medals to be awarded for the best portrait at the forthcoming wandering meeting of the German Photographic Society.

Professor Vogel, having arrived, showed a couple of Obernetter's photogravures after views from nature, which excited considerable interest.

A communication from Dr. Lohse, of the Potsdam Observatory, was then read, in which an account was given of the heliographic work executed at that celebrated institution. Dr. Lohse is just finishing a view of the sun measuring about a foot in diameter, which shows the structure of the sun's surface in a remarkably sharp manner. The mirror of the heliostat must be exposed to the sun as little as possible, or else the heat would change its surface. Then the air must be perfectly still, which it very seldom is, otherwise the picture would be useless. In order to seize a suitable moment Dr. Lohse observed the sun by means of a large reflector placed in a cupola of the building, the heliographic instrument being placed on the ground. The exposure was made by means of an electric attachment connected with the instantaneous shutter.

Professor Vogel spoke about the zinc baths often used for the ferrous oxalate developer. He had been prejudiced against them by finding that certain black specks, which occasionally appeared upon otherwise good dry plates, quite disappeared whenever he gave up employing the zinc dishes and used *carton-pierre* ones instead. Indeed, it had been found that these specks could be artificially produced by means of particles of zinc powder. He thought they were caused by small particles scratched off by the sharp corners of the plates from the surface of the dishes, and that they somehow reached the face of the film. It was also to be remarked that they were not only found when new zinc dishes were used.

Herr Joop recommended for use with the ferrous oxalate developer thin wooden trays coated with asphalte.

Professor Vogel then spoke of his new sensitive-to-colour collodion process. In giving his formula for the silver bath he had forgotten to mention that two to three per cent of alcohol should be added to the sensitising bath, otherwise it would be repelled by the plates. The action of the dyes he had used was very various, and differed with the kind of plates used. The action of the dyes was proportionately smallest with gelatine plates, but there was also great difference between wet collodion and dry collodion plates. Some worked best with wet collodion and some with dry. At present he was directing his attention principally to bromide of silver collodion emulsion plates, on which he found the effect was, on the whole, best; but, unfortunately, the necessary short-fibred cotton was not to be obtained just then. Herr Gädike had given him some beautiful collodion emulsion, but it had proved unsuitable in consequence of the long-fibred cotton from which it had been made. As a matter of curiosity, he mentioned that he had tried a quantity of collodion emulsion six years' old, and found it quite useable and furnishing the best results. It was quite easy to work with collodion emulsion. It could be stained at pleasure by the direct addition of alcoholic solutions of dyes. The plates coated with it were ready for use in a few hours. If it were desired to hasten the drying the plates might be laid upon a vessel containing hot water. The exposure was about three times as long with collodion emulsion as with wet collodion stained plates. The development was alkaline. In ease of manipulation the collodion emulsion process exceeded all others.

The meeting was shortly afterwards adjourned.

Correspondence.

DARK-ROOM ILLUMINATION.

To the Editors.

Gentlemen,—A letter in your last issue from Mr. Andrew Pringle, in which he charges me with want of courtesy, calls for some notice on my part.

It is impossible here to go through the whole of Mr. Pringle's lengthy communications on the subject of the proper light for use in the dark room. The gist of them, however, as I understand, was that different persons found different results in the agreeable character or the reverse of red and yellow light; that whilst admitting that the yellow light which he had tried gave more illuminating power in proportion to its action upon the sensitive plate than the red, yet he personally preferred red, because "yellow-green was obnoxious to him," and that he "deprecated all attempts to lay down the law on such matters for other people." In summing up he said:—"Let the photographer take the one of these colours that he likes best, try his most sensitive plate under the most crucial tests likely to be required, use the most light he can with safety, pay his money, and take his choice."

That there is varying susceptibility to different coloured rays with different individuals I am ready to admit, and have admitted; but I believe that those who find greater "comfort" in the use of red light than of yellow form a very small minority. The receipt of letters containing opinions similar to that expressed in one to hand this morning—"you have been the means of relieving the eyes of others from the dreadful red light that is so painful to most people"—confirms me in this view.

If there be really the conflict that Mr. Pringle supposes in the medical testimony on the matter, let each, meantime, do as Mr. Pringle advised in his first article—decide for himself. I have no doubt as to which colour will generally be found the least trying.

Mr. Pringle's idea that as he had expressed an opinion contrary to mine I was bound in courtesy to give him further "denial or contradiction" seems to me curiously illogical. It appears to me that it is sometimes more courteous to pass over a contradiction rather than to contradict again, and to be eager, in schoolboy style, to have the last word.—I am, yours, &c.,

July 1, 1884. W. E. Debenham.

To the Editors.

Gentlemen,—The vexed question as to which light—that transmitted through a greenish-yellow, or that through a ruby medium—is the best to use in the operating-room will probably never be settled unanimously. No doubt different subjects are variously affected, and the mere statement of a person that he finds the one or other coloured light in all respects the most suitable to work by is likely to be productive of no very conclusive result.

I would suggest a physiological test that may, perhaps, be of use in assisting to decide which light is best adapted for any particular individual. Thus, all things being equal—the same amount of visual power being given, the eyes being exposed to each light for the same duration of time and under similar circumstances, and so on—it is possible that the pupils would, on the admission of white light, become contracted to a greater or less degree in direct proportion to the amount of irritation respectively caused by the differently-coloured rays in the deeper structures of the eyes.—I am, yours, &c., F. R. Fisher.

Grosvenor-street, W., June 30, 1884.

Notes and Queries.

"How shall I prepare silk so as to print upon it?—B. Perkins."——Reply: Dissolve one ounce each of chloride of sodium and gelatine in twenty ounces of water, float the silk upon this for one minute, and when dry excite upon a sixty-grain silver bath. Tone and fix in the same way as for paper prints, and when washed and dried iron between damp cloths.

R. B. wishes to be informed what are the best proportions in which to form the ferrous oxalate developer.——Let him make saturated solutions, in separate bottles, of neutral oxalate of potash and protosulphate of iron, and acidify the latter with sulphuric acid; then, just before using, mix them in the proportion of one part of the iron solution to four of the oxalate. Under certain circumstances the proportions may be one to three; but for general purposes the former proportions will answer best.

George A. French wishes a formula for a developer for eburneum pictures, such as those introduced by Burgess, of Norwich.——We respond by giving the formula employed by Mr. Burgess himself, namely:—

Pyrogallic acid	3 grains.
Citric acid	3 ,,
Glacial acetic acid	10 to 20 minims.
Water	1 ounce.

J. George Gibson wishes to know what course to adopt in order to effect registration of some photographs, and the advantage accruing from such registration.——Let him send unmounted copies to the Publishing Office of this Journal, together with one shilling and sixpence for each photograph, and the Publisher will see that the proper forms are filled up and the registration effected. The advantage is that no one can legally copy a picture after it has been thus "entered at Stationers' Hall."

"Will you inform me how the ready-sensitised paper of commerce is prepared? I would like to be able to prepare some for my own use.—R. A. Larkin."——In reply: Each maker has his own method of preparing it, which he keeps as a trade secret. Some mix the preservative substances with the silver; others float the back of the paper, after sensitising, upon the preservative. Within the past few days we tried a solution of oxalic acid for this purpose, and it toned quite easily. Some employ other acids, such as citric and tartaric; but our correspondent had better make a few trials for himself, and adhere to that which he finds to answer his purpose best.

Rev. F. D. says:—"I have a large and fine graphoscope, the large lens of which shows photographs with very pronounced fringes of prismatic colours. Ought it not to be achromatic? and, if so, would it not then answer ever so much better for showing the colours of the painted photographs of flowers which are seen to such effect in this instrument?"——In reply: For the examination of plain photographs and engravings it would certainly be an improvement to have the lens achromatised; but it would not answer at all in the case of the painted flower subjects spoken of, as the chromatic aberration of the lens is the cause of the relief by which these coloured flowers are characterised when examined in the graphoscope.

London and Provincial writes:—"Apart from the fact of the orthographic lens, as constructed twenty-five years ago, not giving orthographic projection, has it any other fault in consequence of which it could not be employed for rapid landscape or group work? So far as I am able to understand its principle of construction it appears as if great things ought to be expected from it."——We reply: If well made—that is, if the corrections are properly effected—the orthographic lens gives good definition with a moderately-large aperture, and with gelatine dry plates may be employed for portraiture, groups, or landscapes. In the last-mentioned class of subject it may be used with a drop shutter. An opinion has lately been placed upon record that in a modification of this form of objective will be found "the lens of the future."

William Stubbs (Melbourne) sends for examination a panoramic photograph, produced by a camera invented by Mr. John Somerville, Dunedin, New Zealand. The picture is about twenty-four inches long by six inches wide, and is in true panoramic perspective; that is to say, it is not composed of a number of views taken in plane perspective by a wide-angle lens and then joined together. We are asked to give our idea of the utility of such a camera.——In reply: The advent, several years ago, of the pantascopic camera of Johnson and Harrison was hailed with great delight by many on account of the wide angle included and the perfection of the definition. Although several were made, the result, from a commercial point of view, was not considered to justify the continuance of their production. As we have received no information from our friends at the Antipodes as to the mechanical construction of the Dunedin camera, we cannot offer any opinion on its merits. There are, however, numerous subjects for the representation of which a panoramic camera is not only advisable but necessary.

A. J. Macdonald inquires if there be any machine available for coating plates with gelatine emulsion?——From this query we imagine that Mr. Macdonald does not read this Journal very carefully, otherwise he would have seen, several times mentioned, that a machine was patented in this country by an American gentleman a few years ago, and that the patent has now expired. He would have seen, further, an announcement only a fortnight ago that another patent for a second machine had been applied for during the past month.

Exchange Column.

I will exchange, for anything useful in photography, a large mahogany camera (rigid) with four single lenses; would make a good enlarging or copying camera.—Address, J. Edwards, 79, Ashford-road, Eastbourne.

Wanted, a half-plate, square, bellows-body camera, in exchange for a repeating-back camera, to take two *cartes de visite* on half-plate, and a good portrait lens.—Address, F. M. Pugh, 18, Kirchen-road, Ealing Dean, W.

I will exchange a dolphin table, interior and exterior backgrounds, and one large piece of rock (imitation), for a 10 × 8 bellows-body camera with two or more double backs.—Address, Mr. Holgate, photographer, Caryon-street, Burnley.

Wanted, whole-plate (or larger) folding camera with double dark slides, and rapid symmetrical or other good lens; also rolling-press. Will exchange tricycle, pair of silver wine-slides, gold albert, breast-pin, signet ring, half-plate camera, portrait lens, plate-washing trough, and leather case, 13 × 9 × 2¾.—Address, W. L. Knott, 68, King-street, North Shields.

I will exchange cameo press by Marion, cost £5 5s., for cabinets and *cartes*, nearly new; Seavey's boat, *carte* rolling press, lime-light apparatus, lantern, gas-bag, and pressure-board, new; also a set of slides and an oxygen retort. Wanted, 10 × 12 or 8½ × 6½ portable camera, with two or more dark slides, by a good maker.—Address, Mr. Pridgeon, 73, Marlborough-terrace, Newport-street, Swindon, Wilts.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

Photograph Registered.—

Miss Emma Caroline Lawford, The Sisters' House, Fulneck, near Leeds.—*Photograph of Water-Colour Drawing of the Chapel, House of the Principal, and Schools, Fulneck, near Leeds.*

S. R.—Received as we are going to press. In our next.

R. Brooke.—Thanks. By all means send us a report of the meeting in question.

S. S.—One or other of the zinc etching processes will be the best for your present purpose.

Ferrotype.—The *Photographic Times.* Write to Mr. J. J. Atkinson, Manchester-street, Liverpool.

Romany.—Messrs. Marion and Co., Soho-square, will, doubtless, supply the ornamental glasses you require.

Erratum.—In Mr. W. H. Harrison's article last week "phosphorous acid" was by a printer's error given as "phosphorus acid."

N. D. P. Slide.—Your slide is very similar to one patented some time since, except that it is more bulky and somewhat heavier. The slide will be returned.

Turos.—If you refer to our Almanac for the current year you will find the formulæ you require. For fixing, use four ounces of hyposulphite of soda to each pint of water.

E. R.—Ten grains to each grain of gold is the proper proportion to use. It is quite a matter of taste; some prefer one and some the other. Why not give both a trial and judge for yourself?

J. B. Rogers.—Yes; your surmise is quite correct. It is a decided case of green fog, and in its very worst form too. Discard the plates for your most particular work, if not altogether. The latter will be the best course to pursue.

B.—Soak the glass in a strong solution of washing soda or American potash, and afterwards in dilute sulphuric acid. This treatment will render glass which has been employed for collodion negatives perfectly clean, so that it may be utilised for dry plates.

G. E. Williamson and Son.—Mr. Woodbury's stannotype process is patented, so that you will have to secure a license to work it. The Woodburytype patent expired some years ago; hence you can employ that, if you choose. As you are aware, it requires a somewhat expensive plant.

Printer, and One or Two other Correspondents.—To the communications received we do not reply, for the reason that the writers have not conformed to our rule by enclosing their names and addresses. In all instances, when this rule is not complied with, the queries are consigned to the waste-paper basket.

E. J. Wheeler.—If you ask our advice, we should recommend you to defer your experiments in collotype printing until we get somewhat cooler weather. Even in experienced hands this is a troublesome process to work in an elevated temperature. You may certainly expect to meet with difficulties now which will be absent when the temperature is cooler.

Wm. L. Knott.—So far as we can judge from the plan forwarded we fear you will not be able to efficiently utilise the backyard for portraiture. It is so surrounded by high walls, and is so circumscribed in space, that you will practically only get a top light. Your best way will be to build a studio over the whole of the yard, but raising it to the height of the surrounding buildings.

J. Charles.—With the lenses you possess you will have no difficulty whatever in taking breaking waves on plates of moderate rapidity. Your drop shutter is about as good as any you can possess for the purpose.

T. B. L.—Your idea is certainly very good. The india-rubber solution will, to some extent, insulate the print from the cardboard. Should the latter contain anything deleterious to the picture, a greater degree of permanence might be expected from the employment of the india-rubber mountant; but there is the unfortunate fact that the rubber itself perishes—becomes resinised—and then the print comes off the mount.

A Perplexed Printer.—The cause of the hardness of the carbon print is that the tissue is in a too-soluble condition; hence the delicate half-tints wash away. This is a very prevalent trouble during hot weather. The remedy is to bring about a more insoluble condition in the tissue. There are two or three ways of doing this. One is to retard the drying, after it is sensitised, by hanging it in a room where the atmosphere is somewhat moist. Another plan, and the better to adopt when time will permit, is to keep the tissue for several days before attempting to use it. Always keep the developing water as cool as possible.

J. Adams.—A battery of lenses, such as you suggest, would be about the best selection you could make. It is quite true that for large portraits lenses of the "rapid" series can be employed with advantage. If you procure the instrument from either of the two opticians named you may rely upon their quality. The cheap lenses by some of the foreign makers are sometimes very good, but by reason of the small price charged for them not allowing of a very careful examination and correction, they are frequently very inferior. It is much a matter of chance whether you get one of excellent or one of mediocre quality. The form of lenses about which you specially inquire must, in our opinion, be employed with somewhat small apertures, which render them slow in action.

A Risky Job.—The following extract is taken from a letter, dated Mossul, Mesopotamia, written by Dr. Brownski to Professor H. W. Vogel, Berlin:—"Some time ago a happy chance put me in possession of the holy book of the *Jezides*, erroneously called "Devil worshippers" —a book which has hitherto remained secreted and unknown, in spite of the most diligent search after it. This book contains an account of the religion and part of the history of this mystical sect, and there is only one single copy of it in existence. All that Mr. Layard (? Sir Austen Henry Layard) and other authors have written, basing their statements upon hearsay, is false. Intentionally-false statements were made to these gentlemen, and they were imprudent enough to accept them as genuine. They were unaware that the most sacred command addressed to every Jezide is to keep the secrets of his religion (even to the smallest detail) strictly from the knowledge of persons of other religions. The book having fallen into my hands in such a manner that I could only retain possession of it for a few hours, and in order not to thoroughly spoil the whole 'game" (for many persons far more innocent in this respect than I am have gone home headless from the Jeziden districts), as I happened to have a small photographic apparatus at my disposal I copied the book as quickly as possible, page by page. Fortunately all the plates (ferrotypes) turned out well, and now I am engaged in translating this Jeziden bible from the Arabic into German."

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician,
For three Weeks ending July 2, 1884.
These Observations are Taken at 8.30 a.m.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1262. Vol. XXXI.—JULY 11, 1884.

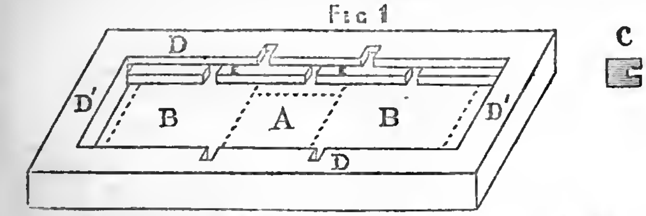
PRINTING STEREOSCOPIC TRANSPARENCIES.

As the subject of stereoscopic transparency printing has been recently revived, and a discussion raised at one of the meetings of the Photographic Club by Mr. Lawrence Baron as to the best methods and appliances to adopt, in response to a wish expressed by one or two friends we propose to describe a printing-frame we devised and had constructed some years ago which, while obviating the necessity for cutting the negatives, enabled the necessary adjustments to be made with rapidity and precision.

In its simplest form—that is to say, when required for use only with negatives of the old stereoscopic size, $6\frac{3}{4} \times 3\frac{1}{4}$—it consisted merely of a negative frame (*fig.* 1) and a sensitive plate-carrier (*fig.* 2) of peculiar construction. The former consists of a sort of tray, about three-quarters of an inch deep, with an aperture A, in the centre of what may be called the bottom B B, of the exact size the pictures are required to be—two and three-quarter to three inches square according to taste; or a shallow rebate may be sunk to receive masks of stout zinc or cardboard, so that the shape and size of the pictures may be varied to suit the subject and circumstances.

The longer sides of the frame consist of mouldings having the section shown at C (*fig.* 1), the ends being solid. On the upper sur-

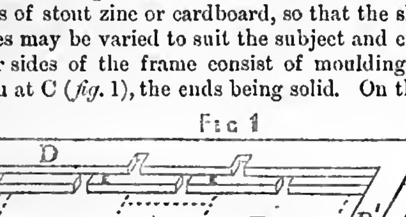
Fig 1



face of each of the sides D D two slots are cut as shown, so that when the plate-carrier is placed in the centre of the frame its projecting runners will drop into the longitudinal grooves E E, only one of which is visible in the diagram, a space of (say) one-eighth of an inch remaining between the lower surface of the plate-carrier and the bottom of the tray. In the lower floor of the groove E at each side are cut three similar slots—one in the centre, the others equidistant therefrom and corresponding with the width apart of the projecting runners of the carrier.

The carrier, which is shown in *fig.* 2, with its under side uppermost, consists of a block of perfectly flat wood half-an-inch thick, three and a-quarter inches wide, and eight and a-quarter inches

FIG. 2

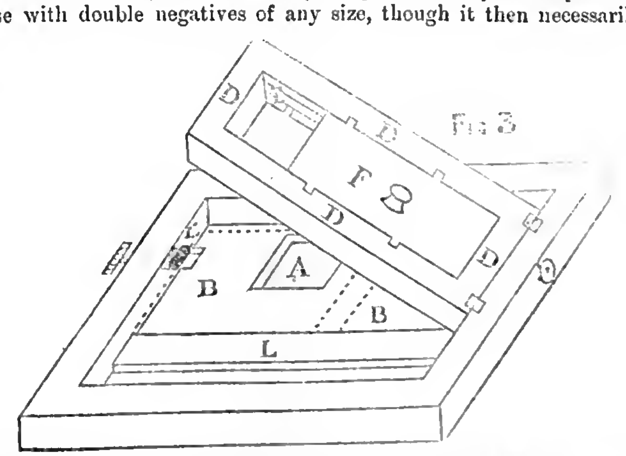


long. Across one end is glued a strip of very hard wood or of brass three-quarters of an inch broad and one-sixteenth thick, with a perfectly square edge. At the opposite end a groove H is cut, three-eighths broad, three-eighths deep, and the same distance from the extremity of the carrier. A strip of very hard wood or brass, J, an eighth of an inch thick and of such length and width that it reaches from side to side of the carrier and projects one-sixteenth of an inch beyond the surface, is kept in position by a good, strong spring or springs, as shown. The projecting runners K K K K may conveniently be made by driving into the sides of the carrier short lengths of brass rod an eighth of an inch or three-sixteenths thick, allowing a-quarter of an inch in length to project. The reverse side of the carrier has a knob by which to hold it.

Now, it will be seen that if a plate measuring $6\frac{3}{4}$ by $3\frac{1}{4}$ (the size of a stereo. slide) be pressed down upon the centre of the block it will be gripped between G and J by the spring, and so securely held. Further: if the carrier with the plate downwards be placed in the centre of the frame D D D D the runners will drop into the longitudinal groove, in which position the carrier may be freely moved to either end of the frame without the surface of the plate coming in contact with anything. But as soon as the carrier reaches the extreme end of the frame its runners on either side coincide with the two of the lower slots, and the plate and carrier drop into contact with the bottom of the tray, in which position—if the respective dimensions of the runners and the slots be properly arranged—there is no chance of abrasion of the contact surfaces by lateral motion.

To use the frame the negative is laid face upwards at one end of the tray, its position being fixed by a strip of thin brass shown by the dotted lines at either end, so that the proper portion comes opposite the aperture A; the carrier, with its sensitive plate, is placed in position and run to *the opposite* end of the frame, when the plate falls into contact with the negative, the left-hand half of the former being superposed upon the right-hand half of the latter, or *vice versa*, and while thus held in contact the first exposure is made. Now, by means of the knob, lift the carrier into the central groove, and while sliding it to the opposite end of the frame incline the latter in the contrary direction, when the relative positions of negative and plate are reversed, and the second exposure is made.

This form is, as we have said, only suited for negatives of the old standard size, but the same principle can easily be adapted for use with double negatives of any size, though it then necessarily



becomes a more complicated arrangement. *Fig.* 3 will, however, sufficiently explain the more complete frame. Here D D D D is again a frame identical in size and construction with *fig.* 1, but *minus* the bottom, which converts it into a tray. F again represents the carrier, which is in every respect similar to *fig.* 2. The tray in this case is separate and the frame attached to it by hinges; its size will depend upon the dimensions of the negatives to be used. In order to permit a three-inch square to be printed from any portion of either half of (say) an 8 × 5 negative it is necessary to provide movable guides regulated by screws, two of which are shown in L and L′, the third, corresponding with L′, being hidden by the hinged frame D D D D. The position of the negative shown by the dotted lines may be varied, by altering the positions of the guides or stops, so that the top right-hand corner or the bottom left-hand or the centre of either half of the negative may be selected.

It would be quite useless to attempt to give working dimensions without knowing the size or sizes of negatives to be employed, the distance apart of the lenses, the distance apart the images are required, and the size of the half pictures—all elements of importance. A frame for $7\frac{1}{2} \times 5$ negatives only may be made whose extreme dimensions will be $12\frac{1}{2} \times 10$, and allow every latitude. If, however, it be required for use with $6\frac{3}{4} \times 3\frac{1}{4}$ negatives as well, more elaborate adjustments would have to be made in order to accommodate the greater range required in the sliding parts. The frame for $6\frac{3}{4} \times 3\frac{1}{4}$ negatives measures about $12 \times 4\frac{3}{4}$, and can be constructed for a few shillings.

Sixteen or seventeen years ago, when stereoscopic work was more in vogue, we had several of these frames made of various sizes for ourselves and friends, and found them a very great convenience, more especially when duplicates were required from the same negative. The adjustment once made, the trouble is no greater and the time occupied longer only by a few seconds than in making a single transparency by superposition.

PERMANENCY AND THE FIXING OF PRINTS.

We now propose to complete our survey of the various causes that may have a tendency under certain conditions to interfere with the stability of a print by referring to the concluding operations of fixing and washing. The story is really a very old one. It is now about a quarter of a century since the theory and practice of fixing was thoroughly investigated, contributors to these columns taking an earnest and important share in the experimental trials and the forming of the resulting theory.

Once more we refer to the old method of toning and fixing, the adoption of which resulted in such a quick and heavy crop of faded prints in some instances, while in others left prints which to this day are in good condition. It was shown that, in many cases, the tone was produced by the aid of sulphur deposited from the decomposed hypo. within the texture of the paper, and, further, that this class of toning led to the production of prints which faded most quickly. The term "sulphur-toning" was devised for this mode of action, and, as was soon seen, it was brought about in many ways, though as these were somewhat intricate as to their chemical bearing they were not understood by non-chemical photographers, who in practice merely followed the indications of their teachers—the experimentalists of the day. They gave up, whether for better or worse, the old "toning-and-fixing" system, and universally adopted that of alkaline toning.

This great step taken, we are afraid that in a sense photographers rested upon their oars. They took some credit to themselves for adopting the process that science suggested. Some rendered themselves thoroughly familiar with its *rationale*, and others had a smattering of knowledge about it; but the greater number of workers looked upon the new system merely as a new recipe. Hence all through the chapter there has been a liability to ignore the main points upon which permanency depended, and, as numerous pictures have been brought before us which have been injured through a want of attention to these matters, it is plain that good may be done by pointing out once more where danger might be imported unawares into the processes involved in completing a silver print.

The main part of the substance removed, after toning, from a print by the "hypo." solution is chloride of silver. This is converted into thiosulphate of silver, and its chlorine goes to form chloride of sodium. Hypo.—correctly termed "thiosulphate of soda"—has the power of dissolving about half its own weight of chloride of silver, its mode of action being first to convert it into thiosulphate of silver, and then to combine with this new salt and form a double salt—thiosulphate of silver and soda—which double salt is soluble in hypo. This seems all very simple, but complex reactions are very readily caused to set in. In the first place, this thiosulphate of silver is very easily decomposed when not combined with hypo.; and, in the next, it is very liable to be formed when there is only a small quantity of "hypo." present. From this it will be gathered that one condition of success is the presence of a sufficiency of hypo. during the fixing of a print. We may here further add that when the double salt is dissolved in hypo. it may be converted into another—an insoluble—double salt when an excess of chloride of silver is presented to it.

This is, perhaps, sufficient of theory to show how we may be guided in fixing a print. If we had all the chloride of silver present in the unfixed print separated and able to be added by degrees to the fixing solution we would find that a quarter of a pound of hypo. will dissolve the contents of a great many sheets of paper. But the very fact of this not being the case is the cause of the large quantity of hypo. which, wisely, has always been recommended to be employed in fixing operations.

Seeing that the hypo. is distributed through a large bulk of liquid, while the chloride of silver lies all within a circumscribed space (the texture of the paper), it follows that unless a large excess be used the conditions will all favour the production of the insoluble salt in the paper itself—a salt which is so unstable that it begins to decompose almost at the instant of forming if there be not more hypo. present.

This, too, is the reason why it has always been recommended to keep the prints moving continually while in the fixing bath. To follow out an instance of the wrong method—that is, leaving the prints to soak without keeping them in motion—we shall see that the first action of the hypo. is to dissolve a layer of chloride from the print and take it up as a double salt. As the solution penetrates the print it contains less and less hypo. as the chloride becomes dissolved, till at last saturation is arrived at, and the action of the chloride of silver still undissolved is to cause a precipitation when it is presented to the restricted layer of liquid held between the prints. This precipitate at once begins to decompose, producing in so doing sulphuric acid and depositing sulphide of silver, the sulphuric acid being ready to decompose fresh hypo. as soon as it comes into contact with it upon the removal or stirring of the prints and the liberation of the changed liquid lying between them.

It is not our intention to enter at all into detail here. We wish broadly to explain the theory undergoing the consistently- and persistently-recommended practice of using a large excess of hypo. in the fixing of prints. Those who wish to have a full account of the original experiments and the theories drawn from them will find almost all they need in vol. vii. of The British Journal of Photography.

We must, finally, point out that in the washing of the prints there is equal risk of producing the dangerous form of silver salt unless intelligent care be taken. When the hypo. solution containing the silver salts is much diluted it is apt to decompose very quickly, especially if it contain a large proportion of silver. These are just the conditions that prevail in washing the print: that portion of fixing solution within the print will—if there be a difference, as is most probable — contain a larger proportion of silver thiosulphate than the bulk of the fixing solution, and so be more prone to decompose; hence, when the prints are placed in the washing water, unless the adherent solution be quickly removed a deposit will certainly occur, and so a want of permanency characterise the print.

We have had prints sent to us many of which were visibly stained through want of this elementary precaution; how many more, therefore, must exist where an equally bad, but at first invisible, effect has been produced! A professional photographer has informed us of a batch of his prints having been once left to a junior hand to finish the washing after fixing, and which were entirely destroyed through his want of attention at this stage. He threw the whole batch into a dish of water, left them there for half-an-hour or so, and then turned the tap on. Almost every print was stained and marked, and it was only through the stains that the way the prints had been treated was discovered. If the carelessness had not been quite so gross the prints would have been circulated bearing within them the seeds of decay, and loss of reputation would have resulted. It is not always that such lack of attention can be detected, and there is little doubt that the fading of many thousands of pictures could be traced to similar causes.

With the use of as few scientific terms as possible we have thus taken our readers over the whole field of the production of a silver print; and it is to be hoped that we may have shown the pitfalls which lie in the way in a manner that will be understood even by the tyro—our remarks, as we stated, having been intended more for the new race of photographers springing up than for the experienced hand.

CALOTYPE OR WAXED PAPER PROCESS.

An allusion to this process in our last number as still being practised by some prompts us to devote a brief space to its consideration, especially as on account of its being the earliest of all negative processes, and its long having fallen into a state of desuetude, comparatively little is known of it by those who have more recently adopted photography as a pastime or profession.

The calotype process was so named by the late Mr. Fox Talbot, its inventor, although by some of the admirers of that gentleman it was designated "Talbotype," its nomenclature afterwards receiving the additional title of the "waxed-paper process," from the circumstance of the paper upon which the negative was taken having been rendered translucent with wax previous to, instead of after, the production upon it of the negative. But notwithstanding the variety of its appellations and, what is of more importance, the variety of formulæ and routine methods of action, the process remained in principle very much the same as when it was first published by Mr. Talbot.

Described in generic form the calotype process, as originally published, included, first, the iodising of a sheet of suitable paper; secondly, the exciting of this paper shortly before using, by means of a solution of nitrate of silver, acidified by acetic acid, with a small addition of gallic acid. The developer was gallic acid, with or without the addition of aceto-nitrate of silver. When fixed and washed the paper was rendered translucent by waxing. By means of this primitive negative process, most admirable portraits, landscapes, and other scenes have been obtained; and, in breadth of effect and other art qualities, some of these early photographs have not yet been very greatly surpassed.

Photography having become a living thing in the hands of many ardent experimentalists it advanced, and, as subsequent history records, has advanced with rapidity. Mr. Talbot's system of iodising the paper was cumbrous, and, when viewed by the light of 1884, somewhat inefficient. He effected this by impregnating the surface of the paper with iodide of silver. This was done by floating the paper upon (or sponging it over with) iodide of potassium in solution, and, after drying, treating it in like manner with nitrate of silver. All the soluble salts were subsequently removed by washing, leaving the paper of a pale primrose colour. A modification of Mr. Talbot's method of iodising was introduced. It consisted in adding a solution of iodide of potassium to one of nitrate of silver, by which iodide of silver was precipitated, which after washing was dissolved in iodide of potassium. This solution was then applied to the paper, and the latter after being dried was floated upon water, by which the iodide of silver was precipitated in a finely-divided form on the paper.

Innumerable were the additions afterwards made to the salting bath; for, not content with dissolving the various ingredients in pure water, many professed to find advantages in employing rice-water and boiled whey instead. Many also were the formulæ for salting communicated to the public, and very heterogeneous were their components. They embraced iodide, bromide, fluoride, and cyanide of potassium; chloride of sodium; sugar of milk, honey, albumen, isinglass, gelatine, gum arabic, and iodine. Things had become much complicated when Mr. Frederick Townshend appeared (just thirty years and one month ago) in the *rôle* of reformer, and demonstrated how simple the process might be made. It would be futile to give here illustrative formulæ showing the progress of improvement; but we may mention one which shows the state in which the negative paper process was left near to the time when the efforts of photographers were being directed towards the attainment of a reliable dry collodion process.

Plain paper is immersed for over an hour in the following:—

Iodide of potassium	15 grains.
Bromide of potassium	5 ,,
Water	1 ounce.

To this sufficient iodine is added to render the solution of a sherry colour. When dry the iodised paper is excited by being floated for about five minutes upon a thirty-grain solution of nitrate of silver to the ounce of water, one minim of acetic acid being added for each grain of silver present. The same precaution must be taken in the formation of this bath as in that for collodion, namely, it must be saturated with iodide of silver previous to being employed. The paper is drawn over a glass rod to remove the surplus solution, and is then blotted off by means of perfectly clean bibulous paper. Paper thus prepared remains good for twelve hours; but if it have to be kept for several days it will then be necessary to float it for from half-a-minute to three minutes upon plain water to remove more of the free nitrate of silver. The longer it is floated the better will it keep, although at the expense of sensitiveness.

The exposure required in the camera was in those early times, when gallic acid was the developer, estimated not by seconds but by minutes. We here allude to the application of the calotype process to landscape photography, a slow lens being employed. With the process as practised by Talbot for portraiture, when gallic acid and aceto-nitrate of silver formed the sensitiser as well as the developer, we have obtained portraits in fifteen seconds, and street views in proportionately less time; but when the paper has been prepared for keeping several hours an exposure of a minute and a-quarter, with a lens working at $\frac{f}{8}$, was necessary.

Upon removing the exposed paper from the dark slide it is floated upon a saturated solution of gallic acid (about three grains per ounce of water), until the details are all visible, when the image will be of an unpleasant red colour, and it may then be completely immersed. After ten or fifteen minutes the image will have acquired great vigour, when a few drops of the sensitising solution may be added to the gallic acid, and the negative again immersed. It now acquires a dark colour very rapidly, and after examining the image by transmitted light, and ascertaining that it is fully developed, the negative is fixed in hyposulphite of soda. Having been afterwards washed and dried the paper is rendered translucent by being waxed. Some have performed this operation by placing the paper on a warm slab, and then applying wax to the surface, which, by melting, impregnated its texture, the surplus being afterwards removed by blotting-paper and a warm flat iron. Others have dissolved the wax in oil of turpentine and immersed the negative in this solution for a brief period.

The advantages of paper over glass for the tourist photographer do not here require mention; but in another article we shall speak of certain refinements upon the process, by which some of the more modern photographic discoveries have been pressed into the service of this the first of all negative processes. The mistake must not be made that, because of the material being paper instead of glass, good detail and sharpness cannot be secured; for, on the contrary, by care in selecting the paper and in focussing, a very sharp image may be obtained.

WHAT IS THE MOST SUITABLE COLOUR FOR A PHOTOGRAPH?

In discussing this subject we set aside all consideration of the vexed question which has been so much discussed of late—that one tint, or tone, may possibly prove of greater permanence than another in silver prints—simply confining ourselves to the subject of the most desirable colour for a photograph, regardless of the means or process by which it is produced. It is quite true that with silver printing the colours to be obtained are very limited indeed, as they are confined to tints ranging from a warm brown, through purple, to a more or less decided black. By the platinotype process both a good sepia colour and a black are obtainable. By the carbon, Woodbury, and the collotype processes any desired colour can be easily produced in the admixture of the pigments employed.

Now, does the public taste demand that all photographs—simply because they are photographs—shall be in the well-known photographic colour and have a glazed surface? It would appear so, if we can take as a criterion the fact that in the majority of cases when pictures are produced by any of the latter processes they are as close imitations of silver prints as it is possible to make them. The tint itself may vary, but the photographic colour is retained. Even in enlargements made in carbon and worked in monochrome the usual photographic tint of brown or purple is, as a rule, employed.

Prior to the advent of photography, it may be mentioned—although prints from engraved plates or wood blocks could, of course, be made in any colour—we have never seen a print produced at that period at all approaching a photographic tint. They were actually produced in almost every colour but that just mentioned, which, in the case of photographs, was, after all, not one of selection but of necessity, and certainly cannot be considered in any way artistic.

Seeing this, it not unnaturally suggests the further query—"Is the ordinary colour and surface of silver prints for ever to be considered the *acme* of perfection in photographs?" We think not, inasmuch as we have noticed during the past year or two unmistakable evidences to the contrary, and that the public taste for certain subjects will demand a variation. It was no uncommon thing, at the last exhibition of the Photographic Society of Great Britain, to overhear visitors remark, while examining pictures by the platinotype process of a sepia or black tone, or by the carbon process of a red chalk, sepia, or black, that they were excellent "because they were so very unlike a photograph." Visitors to the exhibition, for many years past, have been familiar with the charming portraits of children, printed in a red chalk or a sepia colour, by Mr. R. Faulkner and also by Mr. W. J. Byrne, and the admiration they have always commanded—more particularly from the non-photographic portion of the public and the press.

Recently we were shown some excellent cabinet-sized pictures (portraits) which were very artistic, and were also decidedly novel. These were rather large vignetted heads, printed by the carbon process, of a red chalk colour, on somewhat rough drawing-paper. They were mounted on the ordinary cards, but had, apparently, not been rolled so as to destroy the original roughness of the paper; hence they looked very much like small chalk drawings. This appearance would have been enhanced still further had the portraits, instead of being produced with a plain, flat background, been taken with one on which a few hatched lines had previously been made just about where the shoulders of the sitter came.

We have also seen some exceedingly good pictures possessing a certain amount of novelty, chiefly arising from their colour and the style of mounting. These were panel-size portraits—apparently enlargements from smaller negatives—printed in platinum and of a black colour. They were mounted on plate paper with an imitation India tint and wide margin, and had been rolled on a plate so as to give a plate-mark like that in an engraving. Of course they were framed without the ordinary orthodox mount. When completed, these pictures possessed very much the appearance of engravings, as they had—by reason of their colour and matt surface and the style of mounting and framing—lost much of their photographic character. If we mistake not, some pictures very similar to these were shown at the last exhibition—only they were in carbon and, perhaps, of a somewhat blacker colour. For years past, by the carbon process, enlargements have been made on tinted crayon papers, and finished in chalks or crayons; but generally they are made in the usual photographic colour instead of in black, which, in this case, we cannot help thinking would be an improvement.

Hitherto our remarks have chiefly been directed to portraiture, but they apply equally well to landscapes. These, if printed in sepia or black, either by the carbon or platinotype processes, and then mounted on plate paper with the usual Indian paper tint, being also "plate-marked," would prove very effective, as the matt surface of the paper, together with the colour, destroys much of the photographic appearance of the pictures.

In the foregoing remarks we have only alluded to pictures in sepia, black, and red; but of course, if the carbon process be used, any other colour might be substituted. Although, apart from the usual photographic tints, the different coloured tissues obtainable in commerce are somewhat limited, still there is little doubt that if additional colours were in demand they would readily be supplied.

The subject of this article suggested itself from the fact that photographs are now being produced, though to a limited extent, in colours other than the orthodox photographic tint, and that such pictures are apparently much appreciated by the more artistic portion of the public. Therefore, we think that an increased taste for pictures of this character may, with advantage, be cultivated by photographers in the future.

We have carefully re-read Mr. H. B. Berkeley's letter in the Parent Society's *Journal*, without discovering the slightest ground for the charge of "misrepresentation" which he makes against us in his communication this week. That Mr. Berkeley wrote in the interests of the Society, or at least intended to do so, we quite believe; and had he confined himself to the main intention without interfering with the business of journals which have nothing whatever to do with the Society nor the Society with them, all would have been well, and we, at least, should have allowed Mr. Berkeley to air his little grievances in peace. But when "in the interests of the Society" he devotes the greater part of his letter to matters over which the Society has no control—matters, too, nearly affecting the "weekly periodicals"—we felt bound to take some notice of the affair. From what we have already said we have nothing to retract, and it is scarcely worth while saying any more.

At the present time, when a choice recipe for concocting a claret-cup would be more important than the votes on the Franchise Bill, and a rumour that ice had given out would be more disastrous than a drop in consols, there is almost a feeling of satisfaction to be experienced in reading the latest account from the seat of heat. Dr. J. Hilfiker has been taking particular note of the diameter of the solar orb during the last twenty years, and he states that there is evidence of a change in the diameter of the sun according to the frequency of the spots; the more the spots the less the diameter, and *vice versa*. As we have been having a considerable number of these singular visitants of late we may expect the sun's diameter to be reduced, according to Dr. Hilfiker's theory.

Still, whatever the diameter, we have lately had an almost tropical heat, and we have heard of no diminution in the actinic power of the sun's rays having been observed in any quarter. Perhaps the new sunshine recorder, lately described by Professor H. Macleod before the Physical Society, may give us some interesting data as to the recent solar radiation.

At such periods as the present, when the sun obtains its greatest altitude and is not overcast in the middle of the day, there are few studios that do not suffer from the heat, notwithstanding all that may be done to protect them. We have seen automatic ventilators made use of, but the effect has been little proportioned to the expense. Our contemporary *La Nature* has described a new atmospheric turbine which, it appears to us, might with very little trouble be so applied as to work a fan in connection with a ventilating apparatus with some degree of real efficiency. The apparatus is the invention of M. Sanderson, and has already been in use in three separate places, where it has done admirable duty in pumping water, &c. The construction is simple, being merely two semicircular fans mounted at right angles to one another, at an angle of 45° with a shaft working horizontally. Like an ordinary windmill it will work without being set, and whatever the quarter from which the wind blows it is equally potent in a hurricane that would either stop or destroy an ordinary mill. This new motor has been termed by its inventor the "*pantanemone.*"

THE use of a convenient apparatus for regulating the temperature automatically, causing a drying chamber to remain at a constant heat and soforth, is too well known to need attention to be drawn to it. There are many pieces of apparatus for the purpose before the public, each having its own special excellence and, we may add, defects. According to the *Lancet*, however, an important advance in the mode of construction of such instruments has been made by Dr. Reichert, of the University of Philadelphia, who has designed a new thermostat, whose principle of action is essentially the same as that of the older instruments, but which is more efficient in use. The range of temperature is obtained by the employment of a graduated plunger of peculiar make, which forces the column of mercury towards or from the gas regulator, thus arranging for the presence of a greater or less degree of heat to maintain the column of mercury at this point.

THE late Sir W. Siemens, who did so much for the science of lighting, is to have an appropriate monument in Westminster Abbey in the shape of a memorial window, subscriptions to which are limited to one guinea. A very powerful committee has been formed, the Hon. Secretary being Mr. J. Forrest.

WATT'S *Dictionary of Chemistry* is almost a household word. We regret to announce that its talented author is no more. He died suddenly, on the 30th ult., of syncope of the heart. He was engaged at the time of his death in writing a new and abridged edition of his *Dictionary*, also in editing a new edition of Richardson and Watt's *Chemical Technology*, and the thirteenth edition of Fownes' well-known *Manual of Chemistry*—all of which works are of the highest value to the photographer and the chemist.

THERE is every probability that nickel and nickel-coated vessels and instruments will gradually become more general, now that Fleitmann's discovery is so popularised. In 1879 he discovered, by a process of reasoning which proved correct in practice, that the brittleness of pure nickel—which had hitherto been an insuperable obstacle to its extended use—could be got rid of in a simple manner. He considered the unworkable character of the metal (which still prevailed, though it was pure to a fractional percentage) was due to occluded carbonic oxide, and he added a small quantity of magnesium to get rid of the brittleness. The addition was perfectly successful, though even in quantities so small as one-eighth per cent. Metal so treated can be welded at a red heat with iron and steel, and the welded sheet can be rolled out without breach of continuity to a very great extent. For rolling-press rollers and beds such an arrangement should to be of the greatest value.

AN interesting paper by Dr. H. Hager appears in the columns of a foreign journal, treating of matters chemical. It is upon the *Drop Method of Chemical Analysis*, and affords hints for many useful modes of testing some of the chemicals employed in photography. The method is named from the fact that drops only of the material operated upon and the reagents employed are made use of. The list of materials required includes red and blue litmus paper and turmeric paper; extract of indigo paper, which is turned yellow by hot nitric acid and caustic alkalies, but not by ammonia; rosaniline paper, as a test for alcohol; potassium ferrocyanide paper, as a reagent for ferric salts (to which it gives a blue colouration); copper and uranium (deep brown); gold (greenish-brown); platinum (brownish-green to reddish), &c. Potassium sulphocyanide paper is turned decidedly yellow by bismuth nitrate, bluish-black by salts of copper, red by solution of gold, white by mercuric nitrate, black by mercurous nitrate, and blood-red by ferric salts. Potassium iodide paper is turned red by mercuric salts, green by mercurous salts, and yellow by solution of lead. For detecting chlorates: half-a-drachm to a drachm of the liquid is put into a small test tube along with a slip of the paper, half-a-drachm of dilute sulphuric acid added, and heat applied. If a chlorate be present the liquid turns yellow. Mercurous nitrate paper when moistened is turned black in the presence of vapour of ammonia; caustic alkalies and alkaline monocarbonates stain it greenish-brown to black; whilst the alkaline bicarbonates leave it colourless. Silver bichromate paper turns yellow with free hydrochloric acid. The author gives other tests for substances not likely to be met with in photography; but the list above given, as will be seen, is made up in the main of substances likely to be met with on the shelves of the photographer's laboratory. The method of employing the test consists in letting a drop of the liquid, or solution of a solid, fall upon a slip of the paper, and it seems to be so exceedingly simple and useful that we may expect little sets of the test papers to be prepared and offered for sale. They would be of considerable value in the photographer's dark room, if only for the occasional identification of forgotten or unlabelled chemicals.

FILMS DISSOLVING IN THE HYPO. BATH.

IT has been observed that gelatine negatives, if left in the hypo. fixing bath all night, sometimes dissolve from the glass, whilst at other times no such action takes place. This effect of solution came under my own observation for the first time quite recently under circumstances that admitted of some investigation of the phenomenon.

It happened that by an oversight two plates were left in the hypo. baths all night; and in the morning, whilst one was found to be uninjured, the other had lost the film entirely from nearly the whole of the plate, only a slimy, shapeless ridge of gelatine remaining on a small portion of what had been the negative. The plates were from the same batch—two of a dozen of a commercial make that had been obtained to see "what they were like," and then used in the ordinary course. The immediate cause of the dissolving among the film, therefore, had to be sought in the hypo. baths themselves, although it was still possible that the make of plate might have so much to do with it that those of another constitution would resist the solvent action.

On examining the hypo. baths it was noticed that the one which had not injured the negatives was almost perfectly colourless—evidently freshly mixed. The specific gravity of this solution was 1,145, and a measure of a thousand-grain capacity of the liquid was evaporated to dryness in a porcelain dish. This yielded solid matter equal to nearly one-fourth of the whole, showing that there was one part of hyposulphite of soda to about three of water.

The other bath—that which had dissolved the gelatine—was examined, so far as its specific gravity was concerned, and found to be 1,090. It was somewhat discoloured from use, but was not what would be called an old bath. I have an objection to the use of any solution that has become so weak as to require a long time for dissolving the unaltered silver or so contaminated as to stain the film. It unfortunately happened that before I could make a complete examination of the second solution it had been noticed that the vessel was not full, and some fresh, strong solution had been poured in, amounting in quantity probably to about one-third of that which the vessel already contained. It was with the hypo. bath thus altered, therefore, that I was compelled to make my experiments; but the effect of the addition that had been made would probably only diminish its characteristics without entirely removing them, and so, indeed, I found it.

The plates which had been accidentally submitted to the action of the two baths were, as has been stated, of a commercial make. The surface was more matt than in plates of my own make, and the film apparently thinner, although not wanting in opacity, and more easily scratched. These appearances led to the inference that the quantity of gelatine in proportion to the silver haloid present was small. From their rapid fixation and absence of yellow colour in the unexposed film it was probable that no iodide was present.

One of these plates and one of my own manufacture, made with a hard gelatine and containing some iodide, were marked with a diamond, so that each could be easily broken into three parts in the dark room, and were then exposed in a camera, the dark slide of which was arranged to slide so as to give three exposures on each plate, corresponding with the divisions in which the plates were to be broken apart. After development the plates were divided along the diamond marks, and one piece of each was placed in each of the baths as follows:—No. 1 bath was the fresh and strong one, which had not affected the plate in the first instance. No. 2 was the one which had dissolved away the film, but which had been somewhat modified, as described, by the addition to it of about one-third of its bulk of strong solution; and No. 3 was the No. 1 solution diluted with twice its bulk of water. The third bath was made in order to try whether the mere fact of the first bath being stronger was the cause of the immunity from solution of the film left in it, or whether there was something acquired in No. 2 which had produced the solvent action.

In a little time the commercial plate in each bath was fixed. Shortly afterwards the plate containing iodide and immersed in the strong hypo. bath was also fixed, but a considerable time elapsed before those of the same make in the two weak baths were fixed. I may mention, *en passant*, that I have often been surprised to see it recommended to use weak hypo. baths, accompanied by statements that the haloid salts of silver are as rapidly or more rapidly dissolved in them than in a stronger solution.

The plates were left in the baths all night. In the morning those in the first and third baths were found unaltered, but those in the second bath had become softened and slimy, and for some distance round the edge entirely dissolved away. No doubt the addition of fresh solution to No. 2 had so far attenuated its solvent action that it would have required longer time to dissolve the film from the whole of the plate. The fact that No. 3 had suffered no injurious action showed that the solvent power of No. 2 was not due merely to its being a more dilute solution of hypo. than No. 1, but that the property had been acquired.

As the dissolving bath No. 2 had had sufficient plates fixed in it to render it somewhat discoloured, whilst Nos. 1 and 3 had scarcely been used at all, it seemed probable that a certain quantity of ammonia had been carried into it with the developed plates, and that alkalinity might have something to do with the solvent effect upon the gelatine. To see to what extent alkalinity existed, portions measuring one thousand grains each were taken from Nos. 1 and 2. Small quantities of weak hydrochloric acid were added to each by degrees. The acid was that known as the dilute of the pharmacopœia, to one part of which nine parts of water were added. Of this weak solution the fresh bath took thirty minims before any acid reaction was visible on test paper, whilst the other required about thirty-six minims to produce a similar effect. The bath which dissolved the film was, therefore, slightly more alkaline than the other, but the difference in this respect was so very small—requiring only about one-twentieth of a grain of real hydrochloric acid in more than two ounces of solution to equalise it—that the true cause must probably be sought for elsewhere.

If time and opportunity permit I shall probably continue my experiments in the matter; but meantime, perhaps, the indications given will induce some other experimentalists to make further researches into the cause of the peculiar reaction between two of the materials—a gelatine film and a hyposulphite bath—that are now in such constant use. W. E. Debenham.

OXYHYDROGEN EXPLOSIONS.

Not being in the secrets of the manufacturers I cannot say what is the nature of the dust which is found, often very abundantly, in gas bags when, owing to accident or design, the contents of the interior are laid bare; nor am I chemist enough to be able to ascertain this from an inspection of the powder. I presume it to be steatite or French chalk, or some other form of silicate of magnesia, such as powdered talc. Now, as the former of these is represented by ($3\ Mg\ O, 4\ Si\ O_2$), and the latter by ($4\ Mg\ O, 5\ Si\ O_2$), it is not easy to conceive of inflammability as connected with such dust, either in its state of purity or after being subjected to the action of the gases in the bag.

But although *I* am not able to indicate the nature of any change in the powder after its "reposition" in a gas bag, some change appears to be induced, if one may judge of this by the very peculiar smell of the powder after a time. One thing may be assumed, namely, that if the dust be rendered inflammable it scores in favour of the safety of gas bottles as against gas bags.

I do not gather from the article by Mr. Lewis Wright, in the last issue of this Journal, to what extent he understands dust to be productive of explosions of any class; that he disbelieves in it as a cause of gas explosions he has stated. But in instituting a comparison between the United States, where it is well known that gas bottles are extensively used, and this country, where, *as yet*, bags occupy the most prominent position, he cites a witness whose testimony is against himself; for in the New World—where the go-ahead, regardless-of-consequences spirit prevails—we hear very little of explosions arising as a consequence of employing bottles, or even of explosions in themselves irrespective of cause, and this notwithstanding the fact that the lime light is used there to an extent exceeding by fiftyfold its employment in England. I have, fortunately, access to many of the class journals and newspapers of the United States, including those in which the details of gas explosions of all kinds would be recorded, and, so far as I have been able to institute a comparison, oxyhydrogen explosions might be said to be but little known there.

I have yet to learn of the first explosion that has taken place in consequence of a bottle having been used instead of a bag either here or in the United States. I have used both, and give preference to the bottle. Quite realising how unsafe it is to indulge in prophecy, I yet venture to say that in a "few short years" gas bags will be but little known unless as a reminiscence. In this I take ground similar to that of the enthusiast of a former epoch who prophesied the success of steamboats, nothwithstanding the adverse opinions pronounced against them by our own and the French Admiralty authorities, and even by Napoleon himself.

As regards dust as a source of explosion: this terrible force does not appear to be adequately appreciated. It is not yet a period of three years since the destruction took place of one of the largest and finest breweries in the world by fire, directly traceable to the explosion of dust which was being conveyed through an air-shaft, in the vicinity of which a light was burning. This caused much talk in the neighbourhood at the time, and a professor of physical science in one of the universities published a most interesting statement with respect to the length of time required for the destruction by fire of a log of wood, *as* a log, as thin boards, as shavings, and, lastly, as a fine powder suspended in the air. Some suggestive and instructive points on this subject have been given in the New York *Sun* of the 6th ult., an extract from which I may fittingly introduce here:—

"Professor Peck, the chemist, has made some experiments that demonstrate the enormous power of sawdust, various flours, starch, and grain of all kinds. In one of the experiments he took three-quarters of an ounce of starch, and, by raising it as dust in the air, ignited it in a compartment intended to represent a room. When exploded it threw a box weighing six pounds twenty feet into the air. You can judge yourself of the power of the material. Half-an-ounce of starch ignited in the same way was shown by the Professor to lift the cover of a box, and a heavy man standing on it, three inches.

"One of the most dangerous materials is the wheat dust of flour mills. When burned it goes off like a flash. One of the first movements in making flour is to rattle the wheat and pass a heavy draught at the same time over it to carry off the highly inflammable dust. Yet, despite all care, the air often becomes perfectly loaded with it. Prof. Peck has shown what flour would do by taking a box with a capacity of two cubic feet and placing it in a little flour, the light of a lamp entering through a hole in one corner and the muzzle of a bellows through the other. The cover of the box was nailed on, and a man took his place on it. The Professor then worked the bellows, and the small amount of flour within immediately filled the air in the box as dust, the *facsimile* of a dust-laden mill being produced. The flour immediately ignited from the lamp, and in a second the cover was blown off and the man lifted several inches into the air, while a blaze of fire burst out from all sides. A number of interesting experiments were performed by the same gentleman, showing that in our large mills and manufactories where dust was likely to be formed there lurked a power as dreaded as dynamite.

"Peck states that one pound of carbon and two and two-thirds of oxygen, when they combine to produce carbonic acid, will evolve heat sufficient, if applied through a perfect heat engine, to lift nearly 600 tons ten feet into the air. Then he assumes that if forty per cent. of flour is carbon, it would require two and a-half pounds to accomplish this result."

From the above extract it will be seen that dust is an agent of great potency in the production of explosions, although it has not been as yet adequately recognised as such. J. Houston.

COMMERCIAL FABRICS SUITABLE FOR DARK-ROOM ILLUMINATION.

[A communication to the Photographic Society of Great Britain.]

The paper that I have the honour to read before you tonight was intended for our last meeting; but as there was not sufficient time to do justice to the discussion on Mr. Debenham's paper upon the same subject, and to receive my contribution, it was decided to defer both until this evening.

The tone of Mr. Debenham's paper, and the warmth of some of the observations that it elicited at its close, brought to my mind some remarks made by my friend Mr. Bird, at the meeting on March 28th, and which I will venture to quote. Mr. Bird said:—"The great discrepancy between the scientific evidence and the experience of skilled observers indicates that something is wrong somewhere. May it not happen that our knowledge of the chemical effects of the spectrum is not so exact as it might be? When some observers are convinced that a light modified with yellow paper and a green glass will give the maximum of luminosity and the minimum of chemical action, it is bewildering to be assured that spectrum analysis demonstrates the contrary. Further inquiry is necessary to clear up the subject." Exactly so; further inquiry is necessary to clear up the subject. But permit me to ask is there any reason why this inquiry should not be carried on in a friendly spirit—why it is necessary that there should be any personal feeling imported into this question, or any question that may come before the Society? Is it not possible to discuss this matter without ranging ourselves into two hostile camps, the one taking ruby red as their ensign, the other orange? In my contribution to this matter I mean to be *entirely* practical. I have endeavoured to carry out the experiments, the results of which I shall lay before you, with a view to enabling you to pronounce upon certain fabrics, readily procurable, a verdict as to their suitability in all respects for the illumination of the photographer's work-room. I wish to steer entirely clear of all the subjects that excite so much feeling. Spectral analysis, coloured glasses—whether stained red, flashed, canary, green—are all out of my province. The materials I shall recommend are easily procurable, easily adaptable, and in my experience, as a commercial dry-plate maker and user, answer the purpose most thoroughly.

But, first of all, great stress has been laid upon the hurtful effect of red light upon the eyes; but it seems to me as if the persons who urge this argument imagine that those who make and those who use dry plates did nothing but stare at their red light; but in all well-arranged works the eyes of the workers are not directed to the light, but to the work they have to do. The light, whatever it may be, should be arranged to illuminate the work, and shielded from the eyes. When you read a book or write a letter your eyes are directed to your book or paper, not to the light, and the working of dry plates is, or ought to be, no exception to this rule.

As to the real cause of the evil Mr. Bird, I think, hit the matter exactly when he said:—"There can be no doubt that the sudden transition from dark to light is extremely trying to the eyes." If we consider for a moment the anatomy of the eye, we shall soon see how this is. The iris is the thin membranous coating, in the centre of which is seen the pupil of the eye. This pupil varies in size according to the action of the muscular fibres of the iris admitting more or less light into the interior of the eyeball, and the diameter of the pupil is so varied from about $\frac{1}{3}$rd to $\frac{1}{20}$th of an inch. Now these muscular fibres, known as ciliary muscles, are brought into play by the amount of light presented to the eye; the stronger the light the more they contract the pupil, and the weaker the light the greater is the dilation of the pupil. But these muscles come into play comparatively slowly. If you go from bright sunlight into an obscured apartment you can at first see but little; in a short space of time the muscles effect the dilation of the pupil, and you are enabled to see more or less perfectly. On the contrary, you go from an obscured chamber to a brilliant sunlight and you are pained and dazzled by the glare of light; but in a short time the ciliary muscles have succeeded in contracting the pupil of the eye, and, allowing no more light to enter than is requisite, vision becomes normal.

But here comes the moral of the story. The ciliary muscles act *slowly*, and *sudden* transitions from obscurity to bright light are hurtful; the sudden access of light strains the muscles in the effort to rapidly close the pupil. The remedy, of course, is to avoid sudden transitions—if necessary, to wear a veil, or enclose the eyes in protectors of gauze wire and coloured glass of the proper tint when leaving the dark-room.

More than a year ago I read a paper before this Society upon *Photography in Relation to Colour*. It will probably be within the recollection of those who heard that paper, and of those who afterwards read it, as it appeared in the *Journal* of the Society, that of all the coloured bands I exhibited on the screen—which I have again placed before you—the yellow gave a greater sensation of brilliancy to the eye, while its photographic effect upon a bromo-iodised gelatine plate was much less than any of the other colours. This fact, to my mind, showed the direction in which experiment should be made; for, other things being equal, there could be no doubt that the red light then so common for laboratory illumination was *per se* more trying to the eyes than a yellow light. The next step was to discover material easily obtainable, which could be purchased commercially, either of the right tint or capable of being made of the most suitable tint. After some search I have found a fabric called "bookbinders' cloth"—no doubt procurable in many places. My samples were procured at Messrs. Berry and Roberts's, 21, Bride-street, near Ludgate Circus. This fabric, in combination with a yellow paper, procurable wholesale of Messrs. Spalding and Hodge, Drury-lane, and retail at many dealers in photographic goods, has given in my hands a diaphanous screen which, whilst having quite sufficient illuminating power, is absolutely innocuous to the most sensitive plate.

To elucidate the question as to the best colour I fitted up the lantern which I now place before you. You will observe that it is not unlike a magic lantern. It contains a paraffine lamp, and is opaque on three sides; it has a double-bent chimney to prevent the passage of white light and to afford ventilation. The fourth side carries two glasses, connected by a hinge of cloth, and so arranged that pieces of the material to be tested can be readily placed between them. When this apparatus is used the lamp is lighted, the colour or combination to be tested placed between the glasses, and the sensitive plate exposed at a distance of eighteen inches from the screen, through which the light from the lamp must pass to reach the plate.

Before going further permit me to call your attention to a chart of colours and combinations, with their symbols. The symbols have been written on pieces of clear glass the size of the sensitive plates, in bold characters, with opaque varnish. It is evident that the portion of a sensitive plate underneath the characters will have been shielded by them from the light, whilst all the rest of the plate will have been exposed to its full power. Thus, we shall find the characters should come out clear, even though the rest of the plate has been fogged by the action of the coloured light.

THE CHART.

Colours and combinations.	Symbols.
Ruby fabric	R. F.
Orange ,, ...	O. F.
Yellow ,, ...	Y. F.
Ruby and yellow fabric	R. Y: F.
Orange and yellow ,, ...	O. Y. F.
Ruby and orange ,, ...	R. O. F.
Yellow fabric treated with aurine	Au. Y. F.
White paper ,, ...	Au. P.
The above two in combination	Au. Y. F. and Au. P.
Ditto, but with two sheets of the paper ..	Au. Y. F. and Au. P_2.

I made also many experiments with green fabrics of various shades, but I found a tremendous loss of light without the slightest corresponding advantage; and, as I have no wish to overload my paper with useless material, I have thought it best to omit all reference to them, and only to bring before you those experiments which tend to practical usefulness.

I must now ask to have the light lowered, that I may pass before the paraffine lamp in my lantern the various colours and combinations that I have to bring before you.

I place between the glasses with which my lantern is furnished a single piece of the ruby fabric, and also exhibit the sensitive dry plate that has been exposed for five minutes to the light passing through this ruby fabric at a distance of eighteen inches from the coloured screen. Upon the sensitive plate was imposed a piece of clear glass bearing the letter "*R*" in thick opaque pigments. The portion of the plate under the letter has consequently been shielded from the light, whilst the rest of the plate has had the light full upon it for the five minutes. All the plates I shall show you have been fully developed for four minutes with a maximum dose of alkali.

You will see that the *R* comes out clear upon a decidedly dense ground, showing that one thickness of ruby lets through a great deal of actinic light. I now place a piece of the orange fabric in the lantern, and show you the result. You will notice that the orange has been even less efficient than the ruby.

Now we pass on to the yellow fabric. You will notice how much brighter the light appears—that is, there is much greater illuminating power; yet the action upon the sensitive plate is actually *less* than with either the orange or ruby.

We will now put into the lantern combinations of these colours. We will take, first, ruby and orange. The result is still a considerable veiling of the plate. Yellow and orange give less veil than ruby and orange. Ruby and yellow give less veil than either of the other two—due, no doubt, to the protective power of the yellow.

It being quite clear that yellow gives more illumination, and has at anyrate as great a protective influence on the plate as either red or orange, I decided upon adopting yellow as my standard colour; and my experiments were then directed to finding materials most suitable for a coloured screen—whether fabric or paper, or a combination of the two.

I took some thin, close-texture white paper, and coated it on both sides with a solution of aurine in varnish—dry-plate negative varnish one ounce, aurine one drachm. This had the effect of making the paper both tough and transparent. I also coated the yellow fabric with the same solution, and the results I will now place before you.

The first is a single thickness of aurined paper. This shows the veil considerably. I now put in a piece of the yellow fabric treated with aurine. The veil is still there in a very slight degree—much less than with the yellow fabric *minus* the aurine—the illuminating power being about the same. On placing the aurine paper and fabric together we get a screen that gives a good illumination and affects the plate very little. As a matter of practical experience this screen is perfectly safe either for the making or the development of sensitive plates.

I now place in the lantern one piece of yellow fabric and two pieces of aurined paper. This gives a fair amount of light, and its effect upon the sensitive plate is absolutely *nil;* no trace of the lettering can be made out. I consider this last combination absolutely perfect, either for daylight or artificial light, and should have no fear about working in a room lighted by a window of any size if covered by these materials.

As reference has been made to the *greens*, I tried them both as fabrics and coated glasses, and found them eminently unsatisfactory. Whenever a green can be got to have but little influence on the plate it is always terribly low in illuminating power. I have brought a few of my experiments to show you, as the results were at anyrate unexpected by me.

I have here a dark-green fabric, one thickness. It allows very few illuminating rays to pass, yet its action upon the plate is very great. The next is a light green—plenty of illumination, and the action upon the plate actually less than with the dark green. Dark green in combination with orange is better, but a lot of actinic light still passes. Dark green with yellow is a slight improvement upon the former. Light green and orange is actually better than dark green and orange.

I think it is clear that of the three colours experimented upon—yellow, red, and orange—yellow has most illuminating power, combined with the least actinic effort upon the plate. I find, for practical purposes, that one thickness of yellow fabric with one piece of paper treated with aurine to be absolutely perfect, to give a light comparatively pleasant to the eye, and to be perfectly innocuous to the most sensitive plate. For daylight I would advise one thickness of yellow fabric with two thicknesses of aurine paper to form the covering for a window of almost any size, with absolute security.

A most practical and convenient way of arranging these materials for the window of a photographic laboratory I find to be as follows:—Have an inner frame made to the window, let the lower third have another frame, which can be opened to admit white light when necessary; cover this third with one thickness of yellow fabric and two thicknesses of aurine paper. Let the middle portion have one thickness of each; let the top portion have one thickness of fabric. Now, have a rolling-blind, made of American cloth, fitted to the top of the frame. In taking the plates from the packet, placing in the dark slide, and commencing the development, use only the light of the lower third. When the development is well started the blind may be drawn up two-thirds of the way, and when the development is completed the blind may be drawn up entirely, and a flood of useful non-actinic light will pervade the apartment.

In some such way as this the working of dry plates will be found as easy and as pleasant as our old friend collodion. By increasing the quantity of light gradually, the strain on the ciliary muscles of the eye will be reduced to a minimum, and we shall have fewer complaints of damage to the eyesight. J. R. SAWYER.

ON LANDSCAPE PHOTOGRAPHY

[A communication to the Derby Photographic Society.]

THE love of Nature is more or less an inborn feeling belonging to all capable of development and cultivation. It is this feeling which calls forth the Isaak Waltons of our day, from the busy haunts of men, to wander in deep tree-shaded dells where the music of trout-haunted streams charms the ear, or along the margin of rivers, loitering through level meadows whose quiet breadth and beauty delight the eye. Thus the angler gets much of his pleasure from being brought face to face with Nature in her ever-varying beauty.

It is not less so with the pursuit of the landscape photographer in his search after the "beauty-spots" of any locality where he may chance to be wandering; for surely no other calling—or amusement only, it may be—could bring him into such intimate communion with Nature, or afford him such ample opportunities for educating himself into a higher appreciation of the beauty by which he is surrounded. I may carry out the simile of the fisherman and the photographer further in their prospective and retrospective enjoyments; for much of their pleasure lies in anticipation, as it also does in looking back at their journeyings. And as the fisherman recals his piscatorial victories in this and that stream, and the many instances connected therewith, so does the photographer, in an intensified degree, as he turns over the products of his past labours and looks with loving eye on his past achievements with the camera. Every picture he has taken has some tale to tell; and I know of no more pleasurable feelings, after long years have passed away, than those caused by the inspection of a book of old prints taken by one's self. It recals the past more vividly than aught else, and a thousand forgotten events start up in the memory, proving the exposed plate was not the only thing in which an impression had been made.

The advent of gelatine plates has placed in our hands a new power, and brought into the field a host of amateurs who would never otherwise have entered our ranks. When we look back at the toil and labour of a quarter of a century ago—the cleaning of glass, the careful packing of chemicals, baths and dishes, the difficulty of transporting them from place to place, the carrying of water, the smell of chemicals, and the slopping in the stuffy tent—one cannot wonder, now that so many difficulties have been cleared away, at the great accession to our numbers. Even in those days—all difficulties overcome—how delightful it was to carry home the treasured results of a day's labour! Collodio-albumen dry plates—all useful in their day and generation, and slow as they were (fancy standing in a view from three to ten minutes), each had some advantages over the wet ones, for they could be carried about in places where it was hopeless to get your travelling tent.

My last love was the wet plate. It was little trouble to prepare, kept well, and was slow and sure. Slowness was its only fault, and I "stuck to my beer" till only two years ago, for I never had a better or more trustworthy friend.

Of course there were many things we could never hope to get with these slow, old plates, or even with the wet ones. Now we can attempt almost everything with gelatine—from the quietest scene to the restless sea-wave, the rushing train or the rapid movement of a galloping horse, but are constantly reminded that the greater the speed the greater the risk. I have found it so, for I have spoilt more plates during the last two years, *since I gave up beer*, than during the whole of my previous experience.

But I must tell you this is partly owing to trying so many different makers, including some of my own. Let me advise you not to waste time in making plates, but find the one you like best. Let it be as slow as you can get it, and stick to it. Even then you will have failures from the faults of others, through uneven coating, &c. Never mind; if you want to make pictures it leaves you perfectly free to give your whole attention and time to the artistic part of the work. It comes cheaper, and, most likely, better in the end.

We take it, then, that no other occupation gives more advantages to its followers in the study and knowledge of Nature than landscape photography—not even that of the artist; and, though we have not the use and charm of colour, nor the same power of adaptation and selection as our brother of the brush, yet much can be done by the patient and painstaking photographer who bides his time and watches for the best effect before he secures his picture. Like the fisherman who baits his hook with that which is most likely to take his fish, the photographer baits his camera with the best plate he can procure. Both, then, must wait patiently for the proper time to secure their prize.

And now, perhaps, I may offer a few words of advice about this "proper time," and any other matters connected with outdoor work which I may think of as being useful to beginners; for it is to such only that I can hope to make this paper useful. Let us suppose, then, that you are fully equipped with a trustworthy camera and dark slides, a lens or two of different lengths of focus, and that you are possessed of plenty of pluck and patience to bear up against adverse conditions, disappointments, and failures. You have tried your plates and know pretty well how long such and such a lens, with its smallest stop, takes to secure an ordinary well-lighted subject. You drop from the train at some little country station and are eager to begin work. Don't hurry. Wait till you see something really worth taking, and then see that the light comes in the right direction to give your picture the best effect. A cross or side light is generally the best, throwing shadows and bringing out the subject in relief. Never take a view with the sun shining plump behind you, for the result will surely be flat and uninteresting; there will be no contrasting light and shadows to give the charm so essential to a photograph, which has no colour to hide its shortcomings.

In the early days of photography the marvellous amount of detail given by camera work covered all other deficiencies. Its products were looked upon as mechanical miracles which had no connection whatever with the world of art. It is not so now; and he who would excel in his work would do well to study the methods by which our best painters have produced their best effects. A spotless and untouched negative was once the photographer's pride and boast; and no doubt it tended in its day to the production of clean and good mechanical work. Now science and art go hand-in-hand, and few, I presume, will be content with such results as even satisfied the photographer and his friend. Hard representations they were, like soot and whitewash, with great white spaces for the sky—no clouds, no production of light and shade, such as I am thankful to say is now required at our hands. Vertical lines were over everything, but perpendicular to the base of the picture; and sometimes they were bowed not a little, so that a square tower assumed the shape of a barrel.

But all these things are defects of the past, and can be so; and the photographer now rejoices in the possession of such improved lenses and such good cameras that he can use his magic plates—improved, perhaps, more than anything else—to the best advantage, and has little to think about but the artistic part of his work. Let us turn to another phase of the subject. Minute finish in a painting and mere detail in a photograph do not make a picture. Something more is looked for. Elaborate finish in a painting is often a matter of patient, misspent labour rather than the outcome of observant knowledge and brains.

In a photograph the finish *is* there, whether you will it or not—every pebble, every leaf, every twig, and every blade of grass. But to make your photograph a work of art (I use this expression advisedly; for, if you put art into your work, what else is it, whether you use colours or chemicals?), you must see first that your subject composes well—that is, that the principal lines balance each other, and that the distribution of light and shade in masses is harmonious and complete. "How is this to be done?" you say; "we cannot move trees or buildings, neither can we turn on the sunshine in any direction we may wish." No; but the camera may be moved till the very best standpoint is got, the composition may be helped by the introduction of figures and appropriate clouds, and, as for the light and shade, there is no other way than taking the view at the proper time.

It has often been recommended to give up a day to the study and selection of your subject before taking out your camera; and if this were done more frequently we should, no doubt, get better work. The two great points, then, to aim at in your picture are the composition of its main lines or features and its clearness or proper disposition of light and shade. Birket Foster's *Pictures of English Scenery* combine finish with breadth as far as it is possible to go, and come nearer, perhaps, to the work arrived at by the photographer than the production of any other artist. I would recommend this to your notice. Some artists, indeed, give you much finer effect, with great breadth in their treatment. Study all you can, and fuller knowledge will gradually dawn upon you as to what really makes a picture. You will begin to see the *modus operandi* of the painter, and it will be your pleasure to follow him, however imperfectly and humbly.

We need not have any false shame in owning such help as we may thus get, for the assistance we receive is reciprocal. Sometimes there is more art in a really good photographic picture than painters are willing to acknowledge. No class of men are more indebted to the use and beautiful products of photographers than are artists; they make frequent use and get much valuable help and knowledge from the works they often pretend to despise.

The next piece of advice I have to offer is to recommend the use of a note-book wherein to enter every plate you expose—the date, title of subject, time of day, and the kind of light, together with the limit of lens and stop, amount of exposure, and any other remarks you may deem worth recording for future guidance. In the same book, upon developing, note the result. You will find this a valuable book of reference, where you may refresh your memory when doing similar work, and so save many a blunder. New beginners are often surprised and not a little perplexed, when developing a batch of plates, to find one with an exposure of one or two seconds, perhaps, thoroughly exposed, while another exposed three times as long is only half done—all because of the greater difference, not at first appreciated, in the amount and quality of the light. Compare an open, sunlit landscape, contiguous to no very near dark object, with that of a wood scene where the little light one obtains comes filtered through green lenses, and where dark robes of trees come within a few yards of the lenses.

Compare also the taking of the exterior of a church with the interior. In both these cases the difference in the amount of light you are working with is enormous. A ream of such extreme experiences in your note-book is most valuable. A while ago I recommended the use of the slowest gelatine plate you can get because I think they are capable of producing the most uniformly good work, and are more manageable in development; neither is there the same danger of getting them fogged if you use a bag to change them in, as I sometimes do.

Speaking of a changing-bag: I may say you will find this a very useful article; for, besides its first use, it serves as a large focussing-cloth and a protection from rain. But take an umbrella with you on your journeys by all means. It packs easily with the legs of your camera, can be tied to them when not wanted, and will often be found useful to shade the lens or yourself from the sun. Many a time in taking buildings, or, may be, a railway bridge in some exposed situation, an umbrella has been a good friend in warding off the wind and preventing vibration or the overturning even of the camera.

Take also with you on every journey a piece of string. No photographer should ever stir from home without it. I once had the shutter of a 15 × 12 dark slide blown back, snapped off, and carried twenty yards away while stooping for a stone to weight it down, because I had forgotten my string. These are apparently small and trivial matters, but I have recorded a case in *Camera Catastrophes*, published in one of the almanacs, where a piece of string saved me from the loss of many pounds.

I have only lightly touched on a few points relating chiefly to the artistic side of photography. The subject is a wide one and cannot be compassed within the limits of a single paper. Mr. H. P. Robinson has recently published a clever little book, called *Picture-making by Photography*, where you may find many valuable instructions—more particularly, perhaps, as to grouping figures in landscapes, which will lead you much further on in the path I have pointed out.

RICHARD KEENE.

MR. DEBENHAM ON "THE ILLUMINATION OF THE DARK ROOM."

[A communication to the Photographic Society of Great Britain.]

At the last meeting of this Society, when Mr. Debenham read his paper on *The Illumination of the Dark Room*, I brought up the result of a few experiments in connection with this discussion, but the lateness of the hour prevented me bringing them forward. I wish to do so now, and am desirous, at the same time, of drawing attention to a few points in Mr. Debenham's communication.

Here is the result of an experiment to which I referred in the discussion on Captain Abney's paper. A negative is formed of one and two thicknesses of orange paper and canary medium placed side by side. The common orange paper lets through, it will be seen, much more light than the canary medium. Here is a transparency taken by contact, the source of illumination being an ordinary paraffine candle at a distance of twelve inches. At a first glance the orange paper seems to have the best of it, but it will be found on closer inspection that the inequalities in its texture brings it down to about the same level as the canary medium. With two thicknesses the canary medium has a slight advantage in protective power; but the superiority of the orange paper in the illuminating power of the light transmitted is most marked. I show here a similar experiment with canary medium, orange paper, and the yellow paper which Mr. Debenham uses in his lamp. The latter is a thin paper of very uneven texture, but it is a decided improvement on canary medium. Three thicknesses transmit as much illuminating power as two thicknesses of orange paper, the two thicknesses of orange paper being the safer medium, though only slightly so. The weak point, however, in all papers and fabrics is that so much of their safety is due to *general* absorption.

Here is a comparison of orange paper with three coloured glasses. Holes were cut in a sheet of orange paper, a little smaller than the pieces of glass, but corresponding in shape. The paper was then placed on a gelatine plate, with the coloured glasses covering the holes. The edges of the plate were then protected with black velvet placed loosely round, and the whole presented square to a fish-tail gas flame at a distance of four feet. Where the plate was only protected by orange paper (which has already been shown to be about equal in protective power to canary medium, by gas or candle light) the light has had a considerable effect. A slight effect has been produced on the part protected by stained red glass. The second glass—an orange glass, sometimes called "stained red"—shows protective power very little superior to that of the orange paper. The third glass is a piece of very dense ruby, equal in tint to about *three* thicknesses of the ordinary ruby glass. The exposure was not sufficiently prolonged to produce any appreciable effect through it, but its safety is purchased at the expense of illuminating power.

I have here a piece of the stained red glass used in this experiment. A portion of the surface at each end had been removed, leaving the centre untouched.

Here is a plate which was exposed beneath it. The part protected by the central portion of the glass remains untouched with an exposure sufficient to impress the two ends. This slip of glass forms part of a large piece I obtained from a glass merchant at Kensington, and it is similar to the stained red glass used by Captain Abney, which was labelled "Chance's stained red." In his paper of March last, Captain Abney makes use of the expression—"I do not mean orange or flashed silver glass, which is often spoken of as stained red." Before making any experiments, therefore, Mr. Debenham should have endeavoured to obtain the precise glass which Captain Abney used. Instead of doing so, he obtained a glass which he himself describes as a silver flashed glass. In a communication to the Society in February, 1883, Captain Abney describes this silver flashed glass as unsafe, inasmuch as it lets through some ultra-violet rays. The reason why Mr. Debenhan found cathedral green a more protective supplement to it than cobalt glass is therefore apparent. Cobalt glass lets these ultra-violet rays pass through, and cathedral green cuts them off. I may here mention that the rays which produce the greatest effect on bromide of silver are generally recognised to be in the dark blue, not in the violet and ultra-violet, as Mr. Debenham states in his communication. In the experiment by which Mr. Debenham endeavoured to show the inferiority of stained red glass to canary medium, had he used the glass recommended by Captain Abney he would have obtained some such result as I now pass round. Here stained red shows itself superior to orange paper, orange paper to canary medium, canary medium to orange glass, whilst the thinner flashed silver appears very bad indeed. This was taken by lamplight, and is a fairer test than that given by Mr. Debenham; for photographers do not use a light so rich in rays of high refrangibility as that emitted by burning magnesium. But even when so actinic a light as that given by magnesium ribbon is used, the stained red holds its own, and the others appear in the same order. As might be expected, a much stronger impression has been produced through the orange glass on account of the richness of the light in ultra-violet rays.

One word in reference to green glass. I have seen no green glass that does not let any blue light through, and photographers will do well to follow Mr. Debenham's advice to take "obvious precautions" when using a lamp—part of the light from which comes through green glass, unsupplemented with any other colour-absorbing medium. In Mr. Debenham's arrangement for using two lanterns—one glazed with orange-red, and the other with green—the approximation to white light is produced not by the mixture of red and green rays only, but by a mixture of red, orange, yellow, green, and, in a lesser degree, blue rays. Such a mixture of coloured rays is not unlike that which passes through canary medium, excepting that it contains a larger proportion of blue rays, and is therefore less safe, and at the same time whiter.

I beg, finally, to refer to a previous discussion in this room, when Mr. Debenham corrected me for making use of the expression "cathedral green." I have since found that that expression is in common use amongst glass merchants, one of whom showed me a transparent glass which he called "cathedral white." As I see such glasses are quoted in Chance's list as "cathedral tints," *not* "tinted cathedral glass," I consider that myself and others that have spoken of "cathedral green" were perfectly justified in using the expression.

C. RAY WOODS.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

The Exhibition of this Society, for 1884, will be held in the Gallery of the Royal Society of Painters in Water Colours, 5A, Pall Mall East, London, S.W. It will be inaugurated by a *conversazione*, open to members and their friends, at 8 p.m., on Saturday evening, the 4th of October. The Exhibition will remain open daily (Sundays excepted), from Monday, 6th of October, until Thursday, 13th of November. All packing-cases must be sent (carriage paid), addressed to the "Photographic Society of Great Britain," care of Mr. James Bourlet, 17, Nassau-street, Middlesex Hospital, London. They may be sent *before*, but must arrive *not later* than Thursday, September 25th. No packing-cases can be received at the Gallery. Pictures by hand will be received at the Gallery, 5A, Pall Mall East, on Thursday, September 25th, until 9 p.m.

Photographic transparencies will be shown with the Society's optical lantern on Monday evenings during the Exhibition. Slides (which must not exceed 3¼ inches in height) must be sent in either on or before Thursday, September 25th (to come with other exhibits before the judges of awards), and will only be eligible for award when both the negatives and slides are the work of the exhibitor. Each exhibitor must send a letter of advice containing a description of each picture, as also a statement of process and any further detail, to be inserted in the catalogue (and it is suggested that when the work shown is taken by a special process, prepared and made by the exhibitor, information as to particulars should be communicated), addressed to the "Hon. Secretary," Photographic Society of Great Britain, 5A, Pall Mall East, London, S.W.

By Order of the Council.—The rules and regulations respecting the Exhibition are to be strictly adhered to, therefore no picture will be received after nine o'clock p.m., on Thursday, September 25th.

Medals will be placed at the disposal of the judges for artistic, scientific, and technical excellence, and the judges are instructed to reserve three medals for portrait or figure subjects, and one for lantern transparencies (if they find them worthy of awards).

The judges will consist of the following gentlemen:—The President of the Society—James Glaisher, F.R.S., F.R.A.S., &c.; three members of the Council—William Bedford, William F. Donkin, M.A., F.C.S., F.I.C., William England; three members of the Society—John E. Mayall, F.C.S., F.R.M.S., William Mayland, Andrew Pringle.

Any further information respecting the Exhibition and *lantern slides* can be obtained from the Assistant Secretary, Mr. Edwin Cocking, 57, Queen's-road, Peckham, S.E.

ROYAL CORNWALL POLYTECHNIC SOCIETY.

The fifty-first annual report of this Society is before us, and contains the usual mass of technical information in the shape of judges' reports on the exhibits in the different departments at the last exhibition.

The exhibition of the current year will be opened at the Polytechnic Hall, Falmouth, on Tuesday, August 12th, and all pictures for exhibition must be delivered at the Hall not later than Tuesday, August 5th. The following is the list of prizes offered:—

Professional Photographers.—Medals are offered by the Society for meritorious productions in the following subjects:—1, Landscapes; 2, Portraits; 3, Composition Pictures; 4, Instantaneous Pictures; 5, Interiors; 6, Transparencies for Lantern or Window Decoration; 7, Pictures by Improved Processes; 8, Enlargements. All enlargements for competition must be the work of the exhibitor.

Amateurs.—Medals are offered for meritorious productions in this department.

Photographic Appliances.—Medals are offered for improved apparatus and appliances, including magic lantern apparatus, &c. All exhibits in this department must be accompanied by a written explanation of their specialities.

Further particulars may, as usual, be obtained from Mr. William Brooks, Laurel Villa, Wray Park, Reigate.

Putting Designs Upon Glass, &c.

Specification by William Henry Warren, Artist, 5, Suffolk-place, Pall Mall, London.

My invention relates to a method of repeating or duplicating designs upon glass or other material, whereby I am enabled to make exact copies at comparatively small cost.

I take a design etched upon the flat surface of glass in the ordinary way with acid, the etched portions being filled up (say) with lampblack ground in light furniture varnish to a thin paste, in the proportion of about one-third of lampblack to two-thirds of the varnish; or I may use any suitable colouring material for filling up; or I take a design in open work upon a flat surface of any material through parts of which the light cannot penetrate; or I take a plate of glass upon which a design is simply traced in any colour.

This design, hereinafter termed the original, I place against a plate of glass preferably white; but in some cases I use coloured plates, or against any other flat surface previously coated with a preparation such as that hereinafter described, and I expose them to light during (say) about two hours, taking care to place the plates at such an angle that the strongest light obtainable is thrown upon them. I prefer exposing the plain side of the original to the light.

I find that ordinary daylight will give me the desired result; but electric or any suitable artificial light may be used.

After being thus exposed I remove the original and immediately place the plate of glass or other material, hereinafter termed the duplicate, in a darkened room, where it may be kept until required for further operations.

When the duplicate prepared as above described has remained sufficiently long in the darkened room (I have found half-an-hour suffice in most cases, but this will be varied as experience may suggest), I remove it and brush over lightly with turpentine, benzine, or kerosine or coal oil, together or combined, or any equivalent which will remove such portions of the coating with which this duplicate was prepared as have not been acted upon by the light; while the parts which have been exposed to the light remaining hard will not be removed by this brushing, but will form a duplicate design or copy.

I then wash the duplicate thoroughly clean with soapy water, dry it with fine sawdust, and dust it lightly with a feather duster.

Any indentations or slight recesses which have been formed in the duplicate by this brushing, or otherwise, I now fill up with ordinary asphaltum or tracing colour, as is well known to embossers upon glass.

The design being now duplicated upon the glass with even greater exactness than if it had been traced by hand in the ordinary way, but in a comparatively very short time and at immeasurably less cost, it may be simply painted, gilt, silvered, or otherwise prepared; or it may be embossed by etching with acid in the ordinary manner.

That is to say, I build around the duplicate a wall of wax, or I simply coat the back of this plate or sheet with wax, and place in a tank containing an acid—say fluoric acid—of the strength usually employed by embossers in sufficient quantity to cover it sufficiently to permit the acid to eat clean into the plate or sheet to the depth desired. I then pour the acid off and wash clean in cold water, and the plate or sheet is ready for placing in a window sash or for any other application.

I would here observe that in preparing an original design upon ordinary sheet glass I prefer to trace upon what is known as the round or convex side of the sheet; also that I preferably coat the convex side of the sheet on to which I am going to repeat the design with my novel preparation, so that there may be no space between the sheets when placed against each other into which light might penetrate. Where plate glass is used it is obvious that either surface may be employed.

It will be understood that by my process I am enabled to repeat the design any number of times, taking it either from the original traced design or from the copy already produced.

In some cases I take a design, not etched but simply traced in colour upon the glass, and duplicate it by the same method; or I take any open-work pattern—say a piece of lace—and copy it upon glass or other material by coating this glass or other material with a preparation or composition such as is hereinafter described, and by exposing the two together to light and operating as above described.

The novel preparation, which I find may be advantageously used for coating the plate upon which the duplicate design is to be produced before exposing it to the light, hereinafter called Mixture III., I compose in the following manner:—

I take, firstly, asphaltum (I have found what is known as dry Egyptian asphaltum to answer best), say twenty pounds in weight, and place it in any suitable cooking vessel—preferably heated by steam. I then mix it with turpentine until it forms a thick paste, and boil it for about five hours at a moderate heat. I then remove the vessel and allow the mixture to cool sufficiently to permit me to thin it down with turpentine to the consistency of ordinary paint, and, finally, I strain it through a fine sieve into a clean can or receptacle.

I then take (say) two pounds of dry pulverised bichromate of potash and about a-quarter of a pound of tartaric acid, grind the two together fine in spirits of turpentine, and put this into a can, bottle, or other vessel, which I close as hermetically as I conveniently can and set aside in a dark place until I require a portion of it.

I then prepare the following mixtures:—

Mixture No. I.

Alcohol	1 quart.
Tartaric acid	1½ pound.
Crude bichromate of potash	½ ounce.

The whole to be well shaken together.

Mixture No. II.

Alcohol	1 quart.
Tartaric acid	¾ pound.
Mixture No. I.	⅔ gill.

The whole to be well shaken together.

Mixture No. III.

Varnish, such as light furniture varnish	⅛ pint.
Asphaltum, prepared as above described	2/8 ,,
Dry bichromate of potash, previously ground fine in turpentine to form a paste as above described	1 gill.
Lampblack, dissolved in one ounce of the mixture No. II.	1 tablespoonful.

This mixture No. III., having been well stirred and thoroughly combined, should be covered up and placed away in a dark room for about five hours to permit it to settle. The liquid may then be poured into another vessel and is now ready for application with a brush upon the plate upon which the design is to be duplicated as hereinbefore described.

The relative proportions above given are not absolute, but such as I have found to answer well in practice, and, as is obvious, the mixtures and their ingredients may be prepared in any quantity required. Again: for some of the ingredients equivalents may be employed, but those specified will be found successful in practice.

All my preparations should be kept in the dark, and protected from air and light as much as possible.

Having now described the nature of my said invention, and in what manner the same is or may be performed, what I claim and desire to secure by letters patent is:—

1. The method of duplicating or copying designs upon flat surfaces of glass from a design previously etched upon glass, substantially as described.

2. The manufacture of ornamental plates of glass by applying to their surfaces duplicates or copies of previously-prepared or existing designs, substantially as described.

3. The within-described preparation or composition used for coating the surface upon which the design is to be put, compounded of ingredients such as hereinbefore described in about the relative proportions, quantities, and manner set forth and specified.

Improvements in Colouring Photographic Prints.

The specification of William Blair Anderson, photographer, Union-terrace, Aberdeen.

I take an unmounted print (which has been previously toned, fixed, and washed in the usual manner) and mount it on a plate of opal glass or other prepared surface. After pressing out all air-bells it is allowed to dry. Thereafter the plate is heated, and bees'-wax, paraffine, naphtha, or other substance applied till the print is perfectly transparent. The superfluous wax or other substance is then wiped off with a cloth, and when cool the print is gently polished with a silk handkerchief or other suitable soft material, when it is ready for being coloured or painted in monochrome, which is done by the application of oil colours according to the effect desired.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is:—The absolute and exclusive right to take an unmounted print (which has been previously toned and fixed in the usual manner) and to mount it on a plate of opal glass or other suitable or prepared surface, and, after pressing out all air-bells and allowing the same to dry, to heat the plate and apply bees'-wax, paraffine, naphtha, or other substance until the print is perfectly transparent. Then to wipe off the superfluous wax or other substance; and, when cool and gently polished, to colour according to the effect desired by the application of oil colours.

Illuminating by Means of the Incandescence of Refractory Substances.

By Otto Fahnehjelm, Stockholm, Sweden.

The object of this invention is the production of light of superior quality by convenient and economical means.

And this invention relates first to the manufacture of suitable refractory substances in the form of small wire pins or lamellœ, these being fixed in suitable holders that they may be capable of the necessary adjustment; and, secondly, to a method of causing the incandescence of these refractory substances so prepared and arranged by the action of the heat caused by the combustion of the mixture of gases, commonly known as "water gas" in air, at the ordinary pressure and under the ordinary conditions of the atmosphere.

Having thus stated the nature of the said invention, I proceed to describe the manner of carrying it into effect.

The substances out of which the small wire, pins, or lamellœ are constructed are refractory oxides, such as those of magnesium, calcium, zirconium, or silicon, either singly or mixed together in suitable proportions; magnesia has been found to be generally preferable.

A convenient method of manufacturing the small wires, pins, or lamellœ is by well mixing the finely-powdered oxide with a solution of starch, gum, or other gelatinous substance, in such proportions as to obtain a plastic mass. By pressing this through a small hole or die, or by other suitable means, a thread may be obtained of a thickness corresponding with that of the desired wires, pins, or lamellœ. This thread while still soft may be cut into pieces of the required length, and these may be made straight or bent into any suitable form.

This should then be dried and afterwards burnt at a high temperature. If the burning be omitted the said wires, pins, or lamellœ are liable to twist and bend when exposed to the heat of the "water gas" flame.

A number of these small wires, pins, or lamellœ are fixed in rows or rings in a socket or other suitable arrangement, so as to be capable of accurate adjustment in order to obtain the full effect of the heat. Such an aggregation of wires, pins, or lamellœ is termed a "comb."

The socket is preferably constructed of iron, brass, or other suitable metal, and may be in section of a shape of a U. It is filled with a plastic mass, such as damp clay or magnesia, and the wires, pins, or lamellœ are fixed in such a manner as may be desirable by inserting one end in the soft mass, which is afterwards well dried.

These sockets may be straight, curved, or circular, according to the kind of flame to the action of which it is intended to subject the wires, pins, or lamellœ; and they should be provided with ears, loops, or other suitable arrangements for fixing them to a support, by which they are suspended in the flame. This support must be capable of being moved at will in every direction, in order that the necessary adjustments of the comb may be thereby obtained.

If the wires, pins, or lamellœ are bent into the form of loops, a comb may be formed by arranging them on a metal wire or hook. In any case the wires, pins, lamellœ, or combs must be so arranged on the supports that they may be easily replaced, because at the high temperature of the "water gas" flame all the refractory substances of which they are composed are more or less volatile.

The modes of producing "water gas" are well known, and have been made the subjects of several patents. A convenient method of production is by passing steam over coal or coke at a high temperature; the mixture of gases thereby produced consists principally of hydrogen and carbonic oxide.

This "water gas" may be conveniently burnt in gas burners of the form generally used for the combustion of ordinary illuminating coal gas; the description of burner which has been found preferable is that known as a fish-tail burner.

Certain drawings show convenient arrangements of the apparatus. One of these represents a frame made of iron, brass, or other suitable metal. In section it has the form of U. It is filled with a plastic mass, such as moist clay or magnesia, and straight pins are arranged in one or more rows by inserting one end in the soft mass, which is afterwards dried. These frames may be straight or curved. They are provided with means of attachment to a support. These are ears or loops, or a clip. The pins are arranged vertically or horizontally.

In the latter case, when the pins are exposed to the heat of the "water-gas" flame, they bend and assume a vertical position.

A different arrangement is shown, in which loops or hair pins of refractory material are suspended on a hook.

The supports to which the refractory substances are attached can be made capable of the necessary adjustment by means of some such convenient arrangement of screws as shown in the drawings.

The claim is as follows:—First. The manufacture of wires, pins, or lamellœ composed of magnesia, lime, zirconia, silica, or other suitable refractory or fireproof oxide, either singly or mixed together in forms suitable for incandescence when exposed to the heat of a "water gas" flame substantially as described. And, secondly. The use for the production of light by incandescence of oxides of magnesium, calcium, zirconium, silicon, or other similar refractory or fireproof oxides, either singly or mixed together, when such oxides are formed into wires, pins, lamellœ, or other similar shapes, the oxides being acted on by the heat of the flame of "water gas" burning in the air at the ordinary pressure and under the ordinary conditions of the atmosphere substantially as described.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK

Date of Meeting.	Name of Society.	Place of Meeting.
July 15	Bolton Club	The Studio, Chancery-lane.
„ 16	Photographic Club	Anderton's Hotel, Fleet-street.
„ 17	London and Provincial	Masons' Hall, Basinghall-street.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on the 3rd instant, Mr. W. K. Burton occupied the chair.

The Secretary read a letter received from Mr. Beach, of the *Scientific American*, and secretary of the newly-formed Amateur Photographic Society of New York. In addition to referring to the proposed exchanges of minutes, and to a cordial invitation to any of the members of the Society who might be visiting New York, Mr. Beach described particularly some experiments with a modified developer, by Mr. H. J. Newton, the formula for which is as follows:—

No. 1.

Water	12 ounces.
Formic acid	12 minims.
Pyro	48 grains.

No. 2.

Dry carbonate of soda	3 ounces.
Carbonate of potash	3 „
Sulphite of soda	3 „
Water	40 „

To develope: take three-quarters of an ounce of water, a-quarter of an ounce of the alkali solution No. 2, and one ounce of No. 1. It was stated that great latitude was allowable with this developer, and that of two negatives—one of which had received thirty seconds' exposure, and the other only two seconds on the same subject—it was impossible to tell which had had the longer exposure, and that both were perfect negatives.

Mr. W. M. Ashman inquired whether any of the members present had experimented with formic acid in the developer.

Mr. A. L. Henderson had tried some years ago formic acid both in emulsion and developer without finding any advantage.

Mr. Ashman understood from Mr. Beach's letter that it was claimed that formic acid was a developer in itself.

Mr. Henderson believed that formic acid was not a developer but a restrainer, though it did not restrain so powerfully as other acids. About twenty years ago M. Claudet had introduced the use of formic acid in the developer for the purpose of obtaining more rapid exposures.

Mr. W. E. Debenham said that Mr. Maxwell-Lyte had recommended the use of formic acid in the developer some ten years earlier—about the year 1853.

Mr. Henderson thought that glycerine or sugar would answer just as well.

Mr. W. Coles remarked that in American formulæ it should be borne in mind that sixteen ounces, and not twenty ounces, to the pint were intended.

Mr. Debenham said that some time since a member had mentioned that during the hot weather a plate, having been left in the hypo. bath all night, was found in the morning to have the film dissolved away. A similar experience had recently happened to himself. Two plates of the same make were accidently left in the hypo. baths. In one of them (produced) the image had not been affected; from the other (also produced) the film had been almost entirely removed. On examining the baths it was found that the one which had not affected the film was fresh and strong, having a specific gravity of 1,145, whilst the other which had dissolved away the gelatine was, although not what would be considered old, yet somewhat discoloured by use and of specific gravity 1,090.

Mr. HENDERSON suggested that the solvent power of the bath might have been acquired by the small quantities of ammonia carried into it by plates slightly washed after development. He then inquired whether any of the members had noticed an apparent increase in the rapidity of the plates during the recent hot weather. He had done so, and he attributed it to the warmth of the water used in making up the developing solution.

The CHAIRMAN said that according to Captain Abney an increase of the temperature of the plate during exposure conferred increased sensitiveness.

Mr. HENDERSON said that the best of plates, if heated and used when cold again, had become much more rapid.

The CHAIRMAN observed that Captain Abney had stated that complete drying of the plates diminished their sensitiveness two or three times.

Mr. HENDERSON asked whether some one would define what was a hard gelatine—whether it was one that took up a large quantity of water, or what.

Mr. A. COWAN considered it to be a gelatine that made the stiffest jelly with a given quantity of water.

Mr. ASHMAN inquired whether any of the members had tried Mr. Farmer's method of reducing the intensity of gelatine negatives with ferridcyanide of potash and hypo., as recommended by Mr. Coles in his recent lecture. He (Mr. Ashman) considered it the most perfect reducer he had met.

Mr. COWAN also spoke highly of the method.

Mr. COLES said that he preferred to use rather more of the ferridcyanide solution than recommended by Mr. Farmer, so as to get more rapid action.

A MEMBER used the solutions separately, applying the ferridcyanide with a brush and the hypo. afterwards. He also asked what were the conditions by which to get relief in negatives. Sometimes the surface appeared quite flat, and at others with almost as much relief as a Woodburytype film.

The CHAIRMAN suggested partially drying the film with alcohol and then finishing the drying by heat, in order to obtain relief.

Mr. HENDERSON said that pressure on the surface of a gelatine plate, which had been called "shearing stress," produced a mark that had developed opaque. He thought that this effect was continued laterally in the film for a considerable distance from the point of pressure, becoming less by degrees as the distance was greater from the pressure. He had plates which had been packed some time, and he noticed that where the edge of the card had been there was a mark. Under the card itself was clear, and the mark being at the edge he attributed it to a burr having been raised on the card in cutting, thus causing extra pressure there. The mark extended for some distance on the surface of the plate, fading away by degrees.

Mr. DEBENHAM said that such an appearance as Mr. Henderson had described was common on plates that had been kept for some time in an impure atmosphere, and was, he believed, due to the action of sulphuretted hydrogen on the silver compound. The card protected the part of the plate in contact with it, and the film was acted upon nearest to its edges where the circulation of air was greatest.

Mr. W. M. AYRES thought it would be best to make plate-boxes airtight.

DERBY PHOTOGRAPHIC SOCIETY.

A MEETING of this Society was held at the London Restaurant, Irongate, Derby, on Wednesday, the 2nd instant,—Mr. H. Arnold Bemrose in the chair.

The minutes of the previous meeting were read and confirmed. Mr. Male was elected a member of the Society.

Mr. Richard Keene then read his paper *On Landscape Photography*. [See page 440.]

A short conversation followed; and, after a vote of thanks to Mr. Keene, the meeting terminated.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

THE Association met on the 16th May,—Professor H. W. Vogel in the chair. Several new members having been admitted,

Herr BERLIN announced the death, at the age of 70, of Fraulein Bieber, of Hamburg, one of the original members of the Society.

The CHAIRMAN then announced the death of Mr. H. Baden Pritchard, in a few feeling and appropriate words, and the assembly honoured the memory of the deceased in the usual manner, by rising from their seats. He (the Chairman) then made a few remarks regarding a new American weekly journal partly devoted to photography, entitled the *Eye*.

Dr. KAYSER showed a Woodbury gelatine relief and alongside it a lead printing-plate pressed from it, and also a print from the same.

Herr Anders, of Dresden, sent some gelatine negatives intensified blue, agreeably with the process for which he has applied for a patent. There was no accompanying print, and the question whether or not the blue is sensitive to light remains unanswered.

Herr HABERLANDT referred to the fact, observed by himself and others, that under certain conditions alcohol intensifies gelatine negatives. Quite lately he desired to try that method, and laid a finished gelatine plate, while still wet, in alcohol, but after it had dried he found it had not been intensified at all. Consequently he modified the experiment, so as to make it more like what he formerly accidentally observed. He laid the washed plate in alcohol and left it in a current of air until the alcohol dried up by evaporation, and then laid it in some more alcohol. He then got some intensification. He (Herr Haberlandt) called attention to the importance of always preparing the *concave* side of the plate, both in the wet and the dry processes. If the convex side of dry plates were prepared it was very much more liable to injury in packing than the concave side. The concave side was also in several ways the better adapted for exposure.

Herr QUIDDE referred again to the matt streaks he had spoken about at the previous meeting. He had followed the advice then received, and laid the prints separately between sheets of blotting-paper to dry. In order to hasten the drying he had changed the blotting-paper several times, and found that he was no longer troubled by that fault. The same blotting-paper should not, however, be too often used, otherwise it would be apt to cause light yellow specks on the prints.

The CHAIRMAN showed two photographic reproductions of a chromolithograph copied in the usual way, and the other one by his stained collodion process. There was the same difference between them as between the two that were previously described. The grain of the paper on which the chromolithograph was printed was very plainly reproduced in the ordinary copy, but not in the stained collodion copy. The reason given for this was that the shadows cast by the inequalities of the paper of the original were caused by reflected light and were yellowish in tone—a tint to which ordinary collodion is very sensitive, but the stained collodion very much less so; hence these shadows are not strongly reproduced on the latter.

Herr SCHULTZ-HENCKE demonstrated and the CHAIRMAN explained the dusting-on process *(Pizzighelli's Anthracotypie and Cyanotypie)*. The speaker showed a number of finished pictures and a reproduction of a sheet of letterpress printing produced by means of a glass transparency; also some sheets of paper coated with chromated gelatine, which were exposed under a woodcut printed upon ordinary paper, washed in cold water in order to remove the soluble chromate, and then dried. The paper remained white, with slight indications of a design. They were then left for some time in water of 30° R., until the design stood out in relief, dried with blotting-paper, and then rubbed with a brush dipped in dry lampblack. They were then dried, heat being used. The gelatine which had remained soluble, and which formed the drawing became softened and adhered all the more firmly to the lampblack. When all dry the superfluous lampblack was washed off the paper by means of a sponge dipped in cold water, so that the paper reassumed its original white colour, while the lines of the drawing stood out sharp and black. A positive was obtained from a positive, and, being composed of pure carbon, should be quite permanent.

The experiments were followed with great interest.

The CHAIRMAN suggested that Mandel's American lichtpaus pictures, shown at the previous meeting, had been produced similarly.

The meeting was then adjourned.

PHOTOGRAPHIC SOCIETY OF VIENNA.

THIS Society met on the 6th May,—Dr. E. Hornig in the chair. The minutes of the previous meeting having been approved, five new members were admitted.

The CHAIRMAN said he had the pleasure of informing the members that the wish which the Society had long entertained for a photographic experimental studio seemed likely to be realised, for the Minister of Education was inclined to have such a studio built as an adjunct to some new buildings in connection with the Technical Institute. He (the Chairman) then said he was sorry that, owing to the illness of Dr. Eder, that gentleman would not be able to give the lecture for which his name was entered in the programme, *On Experiments with the Relative Values of Light*. He had, however, forwarded the specimens sent by Dr. Vogel to Dr. Eder. The Chairman then spoke at some length regarding Dr. Eder's own researches in the same direction. Some time ago the Society resolved to devote part of the subvention they received from the State to the purchase of a photo-spectrograph, and one was ordered to be made by Steinheil according to Dr. Eder's directions, which it was intended to have been used for testing different lights at the late International Electric Exhibition, but, unfortunately, the instrument was not delivered until after the close of that exhibition. With regard to Dr. Eder's recent labours in the direction of increasing the sensitiveness of gelatino-iodo-chloride of silver plates to yellow, the Chairman thought he could not do better than quote what Dr. Eder himself said in a memorandum in the speaker's possession:—"Experiments with gelatine emulsions containing chloride of silver, chloro-iodide of silver, and chloro-bromide of silver showed that these can be rendered relatively more sensitive to yellow and yellowish-green than bromide of silver can whenever a suitable dyestuff (especially ammoniacal eosine) is added. The sensitiveness to yellow can thereby be enormously increased, and the sensitiveness is, on the whole greater than that of the wet collodion process. On photographing the colour scales I obtained, without the interposition of a sheet of yellow glass—which still further increases the action of yellow pigments—a more powerful action of yellow than of blue. I therefore claim, hereby, the priority of discovery in this matter in so far as that I have recommended that under these conditions chloride of silver, chloro-iodide of silver, and chloro-bromide of silver in the form of gelatine emulsion are relatively more sensitive to yellow than gelatino-bromide of silver, and that I have also published the observation."

Lieut. DAVID demonstrated the use of a squeezing-press, which he had constructed for large quantities of gelatine emulsion. It consisted of a wooden frame and a glass cylinder with a club-shaped stopper affixed to a long screw. At the bottom a sieve made of well-silvered brass is placed. It was difficult to obtain a glass cylinder of sufficient dimensions. Lieut. David also showed an instantaneous shutter, constructed by M. E. Français, and which was applied to the optical centre of the lens.

A number of other articles were exhibited, and some small lichtdrucks by Herr Böttinger were handed round for inspection.

Several publications were laid on the table, amongst others the first numbers of a new French monthly paper *Le Progrès Photographique* (edited by M. Leon Wulff, who published the *Revue Photographique* from 1853 to 1865) and a copy of the second edition of Herr J. Schippany's *Introduction to Dry-Plate Photography for Amateurs, Scientific Men, and Artists.*

The ventilation and cooling of glass houses was discussed in consequence of a query in the question-box. Other questions were asked about antiseptics, Herr Josz's photolithographic process, a new mountant called "alligin" (which none seemed to have tried), and a doubtful point in the regulations respecting the Voigtländer prize competition.

These having been duly dealt with, and some other business transacted, the meeting was adjourned.

Correspondence.

JULY MEETING OF THE PHOTOGRAPHIC SOCIETY OF FRANCE.—"L'EXPOSITION DE L'UNION CENTRALE DES ARTS DÉCORATIFS."—GOLDEN FABRIC.—A CLAIM OF PRIORITY BY M. TAILFER.—A NEW RAPID SHUTTER.—A NEW DARK SLIDE.—M. BORG'S SYSTEM OF DETACHING ALL KINDS OF NEGATIVES FROM THEIR GLASS SUPPORT.—A GOOD FORMULA FOR DIMINISHING INTENSITY.—M. FRANCK DE VILLECHOLLE ON INTENSIFYING GELATINO-BROMIDE PLATES.—PROFESSOR STEBBINO'S INSTANTANEOUS SHUTTER.

THE usual monthly meeting of the Photographic Society of France was held on Friday last, the 4th instant,—M. Davanne in the chair.

The Society was informed that the "Union Centrale des Arts Décoratifs" would shortly open their eighth exhibition, to which photography would be admitted.

The employment of a bath of sulphite of soda was recommended after a negative had been intensified in a solution of bichloride of mercury.

A piece of "golden fabric" was exhibited, which gave rise to some discussion. It may be said that no new light was thrown upon the subject.

M. Attout Tailfer, the maker of the isochromatic gelatino-bromide of silver plates, made a protest against the tendency of the Germans to pirate his patented process, and to publish as their own his mode of working. He drew the attention of the Society to the publications of Vogel, and of Lohse, of Potsdam. The latter had taken his formula to the letter, and was reported as follows in the *Photographisches Archives*:—

"M. Lohse, of Potsdam, has indicated a simple means of preparing isochromatic plates similar to those presented to the Society in 1883 by Messrs. Tailfer and Clayton.

"He (M. Lohse) takes an ordinary gelatino-bromide of silver plate and plunges it into a bath of eosine rendered alkaline by ammonia. The effect obtained depends upon the concentration of the solution of eosine. If the maximum of sensitiveness for the yellow be required it is obtained in mixing—

Water	100 parts.
Eosine	3 ,,
Ammonia	10 ,,

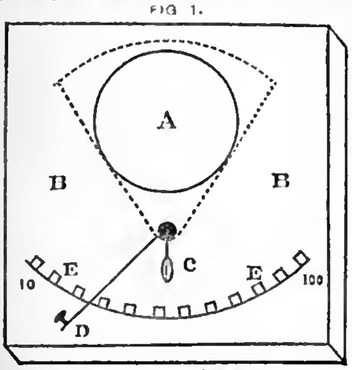
The quantity of eosine which the gelatine absorbs is very small, nevertheless its action is very powerful.

"By employing curcuma instead of eosine better results can be obtained, as the plates are not only sensible to the yellow rays, but all the rays of the spectrum, from the violet to the yellow, have an influence upon the plate. If it be necessary that the yellow should have a predominant action upon the prepared surface it would be probably better to employ a mixture of eosine and curcuma in the solutions."

A long discussion took place, in which it was proved that Major Waterhouse, of Calcutta, was the first to propose colouring the film to obtain different results; then Ducos du Hauron. But the Secretary said that he supposed that the latter gentleman only employed the eosine in collodion emulsions, and not in those of gelatine. I answered that I had prepared plates by staining the gelatine emulsion with eosine for Ducos du Hauron, and for many of his pupils, years ago. A further discussion would have degenerated into the question of commercial rights, &c., so M. Tailfer was requested to address a letter to the Society stating his grievance.

M. Londe presented a new instantaneous shutter made upon the principle of a circular disc. A convenient handle is attached to this disc, by means of which it can be opened and closed. When the handle is moved from left to right it winds up a spring at the same time as the instrument is being got ready for use. This winding up is very little, and therefore gives comparatively slow exposures. M. Londe has made another handle which, moved from left to right, winds up the spring and accelerates the exposure. He drew the attention of the members to the fact that by his system he can change the rapidity at will, and gave the following description: Suppose (said he) that a horse in full gallop is to be taken: the handle is in the cog which gives the most rapid exposure, and all is ready to let fly. By some accident the horse was not taken, and the next object which came in sight was a goat. I have only (said he) to turn the handle to the left; the spring is weakened, and the goat is taken. And so on for every object which passes. I can change immediately the rapidity, which cannot be done by the greater number of shutters in the market.

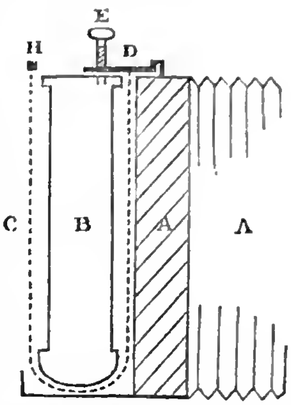
FIG 1.



A, lens. B, square box in wood. C, handle to move disc to set for exposure. D, handle to wind up spring more or less. E, brass cogs to hold handle.

M. Mackenstein presented a curtain dark slide, by means of which one curtain will do for two plates. The slide is very light and well made; its action can be easily understood by looking at *fig.* 2, which represents the dark slide in the camera ready for exposure. In pulling up the curtain C at H the glass is uncovered in the camera. The flange D stops all light from entering. When the first plate is exposed the curtain is pushed into its place and the dark slide turned; the other plate is then ready to be exposed.

FIG. 2.



A, part of camera. B, dark slide (double). C, curtain. D, flange from camera to dark slide. E, screw to fix flange firmly.

At the last meeting of the Society M. Borg, of Bordeaux, had desired M. Audra to communicate to the Society a method by which any gelatino-bromide negative can be detached from its glass support as a film, so that it can be printed from either side. At the eleventh hour that gentleman requested M. Audra not to divulge the secret. It appears that during the month he has had time to change his mind, as M. Audra, in his name, gave a description of the method employed. The negative is plunged into the following solution:—

Water	250 parts.
Hydrofluoric acid	1 part.

The film leaves the glass support with ease, and sometimes stretches out very much. This is very good when the image is extremely dense and an enlargement is wanted. If the film must not stretch the negative is previously dipped in a chrome alum solution.

M. Audra informed the members that the formula given in THE BRITISH JOURNAL OF PHOTOGRAPHY for diminishing the intensity of gelatino-bromide of silver negatives by means of a solution of red prussiate of potash was excellent. This gentleman then made some experiments before the members.

M. Franck de Villecholle made a communication on the intensification of gelatino-bromide plates by means of the mercurial salts. He proposes a second immersion in the hyposulphite of soda bath. If this be done, and followed by plenty of water, the negative will not turn yellow nor be destroyed by time. He proposes the following method. Make three solutions:—

No. 1.	
Water	100 parts.
Bichloride of mercury	2 ,,
No. 2.	
Water	30 parts.
Iodide of potassium	3 ,,
No. 3.	
Water	50 parts.
Hyposulphite of soda	$4\frac{1}{2}$,,

Mix the solutions as usual and plunge in the plate, which will soon attain the required density.

I had the honour to present my instantaneous shutter, which is described in this Journal at page 126, 1881. A modification has been introduced by M. Redier. The pump has been abandoned, and a greater rapidity has been secured. Negatives of children on flying horses and swings were shown as a proof of extreme rapidity.

25, *Rue des Apennins, Paris, July* 7, 1884. E. STEBBING, *Prof.*

CYLINDERS FOR COMPRESSED GAS *VERSUS* GAS BAGS.

To the EDITORS.

GENTLEMEN,—I am not much of a controversialist who prefers to lay down a dictum which shall be accepted as correct; but I do not think a few words, in reply to Mr. Lewis Wright's communication in your last issue, will be out of place.

In the United States cylinders have been in use for years for the production of the lime light. Those made of iron are being displaced by steel, the latter being found tougher and lighter. For medical purposes, and where extreme lightness is a *sine quâ non*, copper ones are used. The pressure employed is fifteen atmospheres, and the vessels contain from ten to one hundred cubic feet.

In England (where strength is universally sacrificed to weight) a small garden roller, called a "bottle," has gas forced into it to forty atmospheres, and is provided with an elegant valve, which generally leaks. My experience is that poisoning the atmosphere is as much thought of as getting a light.

The fact of an explosion at the Royal Institution shows neither want of skill or care. There have been some very ugly accidents there ere now—Sir Humphrey Davy's experience of chloride of nitrogen, for instance.

But at the head and front of all the learned institutions of the world science is considered before danger, and the liquefaction of oxygen (probably the job in hand) is a terrible task—somewhat different to fifteen atmospheres. With regard to the "burning of the iron," also: was it local, or did the "bottle" go off in the shower of sparks, as in the familiar experiment of nails vapourised by the oxyhydrogen blowpipe? There is no danger in anyone pumping their own gas when provision is made for keeping the barrel of the pump cool with water.

The cost of compressed gas and its regulation I will only touch on, as I hope in a very short time to show the latter practically, and to give the name of a manufacturer who is satisfied with a fair profit.

Explosions in the States are very few and far between. The last one was caused by deliberate mixing in the cylinders; and, though the error was pointed out, the mixer preferred sacrificing his life at the shrine of "I know best."

I am not aware what Mr. R. A. Proctor's experiences may be; but, for myself, give me cylinders. They can be used to zero if gas run short—varying pressure does no damage. I have used 50 lbs. in the H vessel, 200 lbs. in the O, with safety—registered by gauge.

All valves or media for preventing pass-backs are worthless. They impede the flow of the gas, choke tubes, interfere with the brilliancy of the light, and are such a cause of annoyance that if Shakspeare had been a lantern manipulator I am certain something else besides physic would have been thrown to the dogs.

On the ground of neatness, saving of room, dispensing with weights, expense, absence of leaks, ease of carriage, and the certainty that no pin will perforate and no guard will cut their tender skin with an iron-bound box, I say the cylinder or "bottle" is *the* thing, and its general adoption is only a matter of time.—I am, yours, &c., JAMES BOWIE.

London, July 7, 1884.

DARK-ROOM ILLUMINATION.

To the EDITORS.

GENTLEMEN,—I am sorry that the wording of my letter to you should appear to attribute want of courtesy to Mr. Debenham, and I beg Mr. Debenham to accept my assurance that my error was not deliberate. I was surprised that the medical evidence I adduced—not my own evidence, which I admit to be of no weight on such matters—should not have some notice taken of it by those who were working to find a light less hurtful to the eyes and to the sensitive plate than ruby. I know some photographers who are pleased with the yellow lights; but I know many more who have tried the yellow and have gone back to the ruby.

I would also submit that what we like best is not always best for us, and those who have long used the ruby and found it harmed their eyes may find the yellow lights produce the same effect in a shorter time. However, I have already placed on record the result of my appeal to medical authority, and shall wait till I see my authority disproved before I put up once more any yellow in my dark room. All I write for at present is to make my apology to Mr. Debenham for my use of the phrase, "want of courtesy."

Mr. Debenham hints at "want of logic" on my part. I leave it to himself whether or not it is logical to expect some kind of contradiction to an argument advanced in good faith and supported by adequate authority, which, if true, would take away the very foundation stone of all his edifice. —I am, yours, &c., ANDREW PRINGLE.

Craigcleugh, Langholm, July 8, 1884.

To the EDITORS.

GENTLEMEN,—I entirely agree with your correspondent, Mr. F. R. Fisher, that the question as to the luminosity and non-actinism of the respective medii of greenish-yellow and ruby is a vexed one.

Mr. A. Pringle, who generally gives the public through your columns so much interesting and, I must add, instructive matter, has, I venture to contend, in this controversy fallen short of his usual "luminosity." He has taken an idea into his head and, Scotchman-like, will accept no compromise, but rides it mercilessly and blindly to the death.

I cannot see what use Mr. Pringle's splendid array of medical testimony may subserve if human nature is so constituted as it is—eyes of so many varied powers, and characters of so many pronounced eccentricities. Physiological tests and professional testimonies go for nothing in a matter of this kind.

As an illustration of what I state let me cite my own experience. Ever since the colour controversy has been started by Mr. W. E. Debenham I have given great attention to the different testimonies, adverse and otherwise, which have appeared on the subject; and I must say—now that they are ended, I hope—I feel perfectly convinced that a great boon has been conferred upon the amateur and professional worker by the happy discovery of a medium which combines the maximum of luminosity with the minimum of actinity. I for one take this opportunity of tendering to Mr. Debenham my most grateful thanks.—I am, yours, &c.,

The Vicarage, Cheadle Hulme, July 8, 1814. H. V. MACDONA, M.A.

TRANSPARENT MARKINGS ON NEGATIVES.

To the EDITORS.

GENTLEMEN,—In your last number Mr. A. Pringle mentions having had several negatives spoiled by a transparent bar at one end, and which he attributes to the emulsion. I think it right to give my experience.

I have had the same on two occasions—spoiling some dozen otherwise very good plates—and on each occasion I was using a new camera by one of the best makers. At first I thought it was the plate; but, as it was always at the same end of the negative, that was impossible. I then noticed it exactly corresponded with the hinges, and in some cases showed the divisions; and, on referring to my notes, found the plates had all been exposed or retained in the slides in very hot weather. So there can be no doubt the india-rubber American cloth used was the cause—possibly not being sufficiently seasoned.

With some makers' plates the reverse effect was produced. In cool weather I have not noticed any mark.—I am, yours, &c., D. W. HILL.

London, July 5, 1884.

PRINTING-INK MARKINGS ON NEGATIVES.

To the EDITORS.

GENTLEMEN,—In packing some exposed gelatine plates recently I was foolish enough to place slips of *newspaper* between each. As might have been expected, the film appears to have absorbed a portion of the printing ink, with the result that on development the marks of the print appear more or less clearly in all the negatives. Will you kindly say in your *Notes and Queries'* column whether there is any method by which the marks in question can be removed?

As an experiment I have soaked a plate in benzole, and after half-an-hour's immersion the marks certainly appear to be fainter, although they were not nearly eradicated. Thanking you by anticipation,—I am, yours, &c., S. CASBOURNE.

Companies' Registration Office, Somerset House, W.C., July 8, 1884.

[We cannot suggest any better course than that adopted, unless it might be to preface it with ammonia treatment.—EDS.]

TONE IN SILVER PRINTS.

To the EDITORS.

GENTLEMEN,—On the subject of "tone" in silver prints, I have not noticed that attention has been directed to the subject of that important factor, namely, gold.

The cutting tendencies of the times may, alas! have endangered the purity of the "noble metals," and it behoves all to be certain that the salts of the metal they use are of guaranteed purity. There is a good opening for a public-spirited individual to make an analysis of the various advertising samples of gold, and report the result of his researches through the medium of your columns.

I always purchase those of the best makers, leaving it to those fortunate individuals to experiment in the direction of economy who possess more profound chemical knowledge than does—Yours, &c.,

28, *Rockley-road, West Kensington Park, July* 7, 1884. C. J. LAMBE EAMES.

THE PHOTOGRAPHIC SOCIETY: ITS REPORTS AND THE PHOTOGRAPHIC PRESS.—A REPLY.

To the EDITORS.

GENTLEMEN,—The storm of righteous indignation which my luckless suggestions, published in the *Photographic Journal*, raised in these columns having now apparently abated, I raise my head again and look with awe after the departing anonymous ones who arrayed themselves in column against me and "came down" on me "like a load of bricks." No doubt these gentlemen did not forget to let the Editors into the secret of the appellations by which, on occasions demanding less righteous indignation, they are generally known. By the way, would not remarks upon such subjects as those of my letter carry more weight were writers of them to append their names thereto? Publishers of new processes and humble inquirers after information may well adopt the *nom de plume* if their modesty urge them to do so; but remarks bearing upon the action or statements of an individual, to my mind, should always be signed by the writer of them. Modesty is here out of place. But, stay; why make suggestions?

Really, if these modest writers peruse the reports in the same inaccurate manner in which they have read my remarks I can well understand how it is that they pass over unnoticed mistakes and omissions in the former. For they seek to make me responsible not so much for my own opinions as for those of others, or for projects existing only in their own imaginations.

I propose to give answers to several of the statements which these and other writers, as well as yourselves, have made; but, before doing so, I must point out that my suggestions were made, not so much with a view to the interests of the weekly photographic periodicals, with which I have only the ordinary connection of a reader, but with the object of furthering, as I think, the wellbeing and status, as a scientific body, of the society of which I am a member, and in which, as such, I am bound ("logically," Mr. "Free Lance," though some do not seem to be of this way of thinking) to take an interest. Accuracy is essential in the *Transactions* of a society; no statements made in a formal manner during the sittings of such a society should be lightly omitted. That which one man may take to be "bosh" another will think highly of; and who is to judge whether So-and so's remarks are to be "put in" or "left out?"

Now, I have been accused of not being logical in my advice, and one of the anonymous thanks me for helping him to the term "corrected (presumably) report." Well, as I have said, I wrote to and for the *Photographic Journal*, or *Transactions* of the Photographic Society of Great Britain, and not for any other, though I suggested that my plan, if carried out, would not be to the detriment of the weekly press. I wrote in favour of the welfare of the Society as a society, and not for such individuals as do not mind with the one hand subscribing their guinea and with the other doing all they can to decry its operations. "Where is the logic here?" This being so, and to be fair and, indeed, "logical," I had to interpolate "presumably" between the above words for the reason that, while I was suggesting the advisability of the reports being made so perfect that they could with certain advantage be copied by the weekly press, the *current* reports of which I complained did not warrant my assuming the marked superiority for them my suggestions would infer. But, seeing that the arrangements and opportunity which the Society possesses are so easily brought to bear, I could see no reason why the reports in the future should not be accurate—not necessarily in *word*, Messrs. Editors, but in *substance*—and thus well worthy the attention of the weekly press.

A general report might well be given in the weekly press as soon after meetings as the Editors may find possible; but I think it would be well that such report should not pass as, be confounded with, or be in place of, the official report, which might be extracted with the papers from the Society's *Transactions*. Such a course would be one of courtesy and justice to the leading photographic society in this country. I am sure I am not inclined to be behindhand in regretting the tardy appearance of the Society's *Journal*. Perhaps under some conditions—not aided, however, by "heaving half a brick"—an earlier appearance might be possible; but, in mooting this, I have no intention of "looking a gift horse in the mouth." Those who think they have an infallible cure for the delay will perhaps not "hide their light under a bushel," neither their names under *noms de plume*. I suspect any good offer on this score would be jumped at by the present editor. Now, please, don't all apply at once.

In regard to Mr. W. E. Debenham's objections to the "slip system:" may I suggest that it would be more complimentary to his fellow-members were he to give them credit for not seizing opportunities for "cooking" the reports in order to suit their own views or to damage the value of the remarks of others. My opinion of men is higher than that of Mr. Debenham; and though I think a slight polishing of the words might take place (mind, the present reports in no publication are by any means verbal, the actual words of the speaker being seldom given), yet the meaning and sequence would remain. And even if this were not always the case, such reports, if passed over by the editor, would be open to correction in the subsequent *Transactions* of the Society. Anyone who may be wronged or misrepresented may make his statement in the Society's *Journal*, as at present under other circumstances. But how often would such a protest be required? Seldom, I venture to say.

In regard to the circulation of the Society's *Journal*: I take it that the whole object of the existence of a Society's *Transactions* is gained when they have placed on record correctly and officially the business of the Society which issues them. Should the *Journal* circulate outside the body of members, so much the better for the outside as well as for the coffers of the Society. But no circulation at all (that among members, of course, not being referred to, seeing that each member is bound to receive copies in virtue of his membership) is no sufficient reason for urging the uselessness of such an organ. Every scientific body of any importance has an official organ, in which its transactions are recorded; and why is the Photographic Society of Great Britain to be niggardly in this respect? A society no more than an individual should not rely totally upon the efforts and goodwill of others, but keep its own house and its own books, so to speak. This, also, in answer to Mr. Andrew Pringle.

The gentleman just mentioned is not the only writer who has misrepresented, or misread, my letter. I do not suppose I can go into the whole of the points where my views differ, or are made to differ, from those of the writers; but I shall indicate several of them.

Mr. Pringle, after writing to say that he "had to read repeatedly and carefully" before he arrived at my meaning, proceeds to indict me on a twofold accusation, neither part of which can justly be brought against me. Plainly, then, this time:—I did *not* write that "the papers to be read at meetings of societies should be printed before the meetings" (though one of the anonymous did so). I wrote "that the paper read requires *publication* rather before the remarks made upon it than after them." This must be patent to anyone who will think. The present plan is like "putting the cart before the horse." It is the paper which calls forth the discussion, and for precisely similar reasons the reader should peruse the paper before he can understand the full meaning of the remarks bearing upon it. On this there can be no two opinions. I did not refer to the printing of the papers before the reading of them. (By-the-bye, Mr. Pringle's objections to this would have more weight were it not possible in such case to allow the readers of such printed papers to add subsequently to the reading any remarks which they added and spoke during the reading of their papers. But I do not propose to go into this subject, which I did not touch upon.)

Then, for the second accusation: Mr. Pringle is again mistaken. I do not say that "the public periodicals should not be allowed to publish remarks until they are issued in the Society's *Journal*." On the contrary, so long as it is found impossible to publish the *Transactions* earlier I place considerable value upon the reports we now find in the "public periodicals" (though the papers do not accompany them). I really only find fault with the "public periodicals" in so far as, while they are glad to avail themselves of the Society's papers, they refuse to publish the full and official reports at the same time. Having stated this I will acknowledge that the independent reports of the weekly press have a value of their own. I contend that the publication of both paper and report in the same issue would be valuable to those readers whom the Society does not number among its members. Mr. Pringle's postscript "cuts two ways." Anyone paying a guinea a year subscription for membership has a right to expect that the necessarily small ways of minor and poorer societies may be dispensed with.

Now, in regard to the Editors' remarks. Like the other writers, the Editors totally misrepresent my meaning. The words I used are "errors and omissions;" I wrote nothing of condemning "condensation, while retaining" the "sense." As I have stated, I think the outlines of the business of the Society given in the weekly press answer admirably generally as far as they go; I only say that *as reports of the transactions of the Society* (for this they really are to the non-member reader) they might be more perfect with advantage, and this not merely *verbally* but *substantially*. The Editors cannot have failed to see that I have proved even the official reports to be not perfect. How, then, are they likely to exceed these in accuracy? The members of the Photographic Society of Great Britain should feel highly gratified to learn that the reports of their meetings "occupy at least as much space and are quite as accurate as those of any of the numerous other societies whose proceedings" are recorded. The wording of this passage is rather suggestive of occasional slips in the reports of the meetings of "other societies." Now, no doubt the secretaries of the "other societies" do their best to furnish correct reports, and the editors do their part in inserting these in their papers, and all is done as well as circumstances permit; but in the case which we are now discussing there are facilities—provided the "slip system" is properly carried out—for obtaining correct and full reports by extracting them from the *Journal* of the Society. But, of course, if the editors and their general readers place no value upon these, probably the Society will not suffer much, and I have nothing more to write on that point.

I do not know how the Editors would defend the system of publishing the "reports" *only* weeks before the papers appear in their columns. How much better that they should also appear together! Photography is not like the "latest news" in a daily paper; if what is said is of any value, it will not be the worse for keeping, and will not lose its point by appearing with the context, but, on the contrary, gain in force of meaning.

One more point and I shall have done with the Editors. Whether "the speaker himself is the best judge" on all occasions of the *exact words* he used may be a moot question; but there can be no doubt that a speaker knows best what he intended to convey, and—*pace*, Mr. Debenham—I contend that there can be no harm in his making an honest alteration of verbiage (the reporters do not take down the words as uttered) so as to set forth what he thinks he said. One does not like to see one's remarks made a complete hash; and it is one duty of a reporter to present a speaker's meaning without any incoherences of expression. If, therefore, a member receiving his "slip" do not recognise either his words or his meaning thereon, he is entitled to make the necessary corrections to convey that meaning. But how shall it be when a speaker is omitted from the report altogether? Truly there will have been a *slip* in sending him no "slip!"

"One Who Seldom Misses a Meeting" informs us that "few of the members besides Mr. Berkeley would object to the publication of the papers a day or two after they are read," &c. If this gentleman who does not miss meetings will refer to my letter again he will find that he *will* "miss" any statement of mine to that effect. Again, why don't people *read!*

Why does not "Looker-On" and "Listener" favour the Society with some of their "luminous ideas"—by the way, are they upon "light in the dark-room?"—during the formal proceedings now so stale and unprofitable, and not keep hidden so valuable matter as he and his friends barter over the "attractions of the refreshment table?" (It is really comforting to hear that the Society possesses at least *one* "attraction.") If he do not see his way to conferring this inestimable benefit, let him not poke fun (as does also "One Who Seldom Misses," &c.) at those on whose shoulders the real work falls. This writer also falls into the error (why, I cannot say) of making it appear that I am moving for a report of proceedings *as delivered*. I did nothing of the kind. Let him also re-read my letter.

Now for "Free Lance." He is nothing if not sarcastic. *That* is the "logical" sequence of his poke at me. It is "Free Lance's" *point* to find a *butt* wherever he is able. I did not infer in my letter that errors must occur in "all summaries" or reports, as "Free Lance" seeks to make it appear. I merely wrote that "such errors must remain inevitable"—of course, as at present appearing, with more or less frequency, and not in "all summaries." I do not know what "Free Lance's" experience may be, but my own is that if I know much of such and such a subject, or of such and such a history, or incident, or series of incidents, often as not I find errors and omissions of a most misleading character, and these totally due to the writer of the report. And, what is more, Messrs. Editors and "Free Lance," I do not find this so only in the pages of the photographic press, but also in almost all journals I may take up; but, of course, some papers are greater sinners than others in this respect. "Where is the logic here?" It is logical to suppose that the editors of these papers have no means for ascertaining the correctness of reports furnished to them by their reporters, and for obtaining the correct versions when the former ones have been proved to be faulty. But I take the view that the editor of the *Journal* of the Society has exceptional facilities for obtaining by the "slip system" what are substantially true reports of the transactions; and, granted that these facilities are taken advantage of, the apparently much-piqued Editors have every opportunity for doing complete justice to the principal photographic society in this country, while, at the same time, the papers published are more fully elucidated for the benefit of the entire photographic community.

I believe that most (if not all) of the provincial societies furnish to the photographic press what may be termed "official reports," these being drawn up by the respective secretaries of the societies. In the name of all that is "logical," why is the Photographic Society of Great Britain to be stinted of its official report, while the newest and smallest society in the kingdom may furnish such reports as it thinks fit and see them appear *in toto* in the weekly press? Merely because the Editors in the former case see fit to present their readers with an early skeleton sketch — praiseworthy enough *as a sketch*—of the proceedings, making, as they allege, the full and official and correct report superfluous. But, as I have said before, is this action complimentary to the Society? The object should be not to supplant the official report, but to give as early an account as possible of what will appear more fully in that report.

But, of course, much hangs on the question whether the Photographic Society is rather to be made much of on the one hand, or to be snubbed considerably on the other. Surely the editors of the photographic press have the interests of the Society—on whose Council some of them are—entirely at heart. I do not think otherwise. But do they do their best to show it? There are many other points on which I could touch, but space does not permit.—I am, yours, &c., HERBERT B. BERKELEY.

July 5, 1884.

Notes and Queries.

A. B. inquires:—"How can I make a white varnish to apply to a ferrotype plate which will dry quickly and smoothly?"——In reply: Mix a white pigment, such as oxide of zinc, with collodion, and a varnish possessing the two properties named will have been obtained. We cannot offer any further suggestion unless we are informed of the purpose for which the varnish is required.

George Rossiter has heard of something other than acetic acid which, when mixed with the iron developer, renders it especially useful in giving intense, clean lines when copying engravings. He wishes information respecting this.——In reply: Certain preparations of gelatine will confer this quality. Dissolve this substance in sulphuric or acetic acid, and add a few drops to the developer.

Rev. B. Fraser inquires—"Is it safe for me to employ gutta-percha pipes through which to convey water for photographic purposes? The pipes are new and clean, and I have been assured by the dealer from whom I purchased them that water has no action on them. What is your opinion?"——We reply that gutta-percha tubing has a good reputation as not having any deleterious effect or action upon distilled water.

J. Rayner says:—"I have a single landscape lens which, when used with the largest stop, does not quite cover the corners of the plate, and if I use a smaller stop still less of the plate is covered. I only use the lens for half-plates, for which size it was made. Am I right in supposing that the fault is caused by the stops being placed too far from the glass? And, if so, could it easily be altered?"——In reply: Our correspondent is quite right concerning the cause of the dark corners. The facility with which it can be remedied depends upon the construction of the brasswork.

"Do you know of any place in this country where I can procure photographs of Mexico and Central America? I have made application at the establishments of several dealers in photographs in London without having been successful.—Yours, &c., T. S. Boyd."——In reply: If any reader can afford the information we shall be glad. We are aware of Mr. Muybridge having several years ago published a catalogue of such views, but we are unaware of his having an agent in this country. Probably they may be obtained by ordering through any American bookseller or photographic warehouseman.

G. T. Scott writes:—"I am troubled by the foregrounds of my landscapes being much darker than they ought to be, this being quite irrespective of exposure. By being darker I, of course, mean by contrast with the distance. Can you give me a hint by which this can be prevented?"——In reply: The most obvious method of preventing the fault complained of is to place the diaphragm at an angle, so as to face the foreground. In this way a larger beam of light will be transmitted from it to the plate than comes from the distance, thus correcting in some degree, if not entirely, the evil complained of by our correspondent.

J. T. Watson wishes to know "which is the best book on photography."——To this we reply that if The British Journal of Photography and its accompanying Almanacs do not fulfil this description it is not for want of effort on the part of all connected with them that they do not do so. But perhaps Mr. Watson refers more particularly to the numerous manuals that have been published on the subject. To indicate a preference for any of these would be invidious. A few shillings spent in this class of literature will place our correspondent in a position to decide for himself, and the investment will be a sound one.

P. D. T.—Our correspondent desires to receive some information respecting the action of a lead salt in printing. He has seen reference made to it, but has failed to discover any article treating practically on this subject.——In reply: We presume that what is meant is the employment of an acetate or nitrate of lead bath in which to place the prints after their removal from the hyposulphite of soda, and having been subjected to a slight washing. The following directions will suffice:—Dissolve two ounces of the salt in a pint of hot water. This forms a stock solution. The prints, after removal from the fixing bath, are rinsed in several changes of water and transferred to a vessel containing four quarts of water and two ounces of the stock lead solution. After a few minutes the prints are again well rinsed.

Exchange Column.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

Photographs Registered.—

Joseph Stephen Brown, High-street, Bridgewater.—*Three Group Photographs of Clergymen.*

William Pankhurst Marsh, Norfolk Cottage, Bognor.—*Two Photographs of the Merchant Taylors' Convalescent Home, Bognor;* also *Photograph of St. Michael's School, Upper Bognor.*

Z. X. Y.—The best plan is to place a wet cloth at the bottom of the camera during the exposure. This will greatly retard the drying of the plate.

E. A.—You cannot do better than make your requirements known through the advertisement columns of the Journal. They will then, doubtless, be easily met.

W. J.—The transparency sent is not an albumen one, but, apparently, has been produced by the wet-collodion process, and then toned with mercury followed by ammonia.

J. J. J.—In former times it was by no means unusual to glaze the studio with blue glass, but it is very seldom done now. Our advice is to use ordinary sheet glass, and then subdue the light with suitable blinds.

A. Newman.—The thin sheets of gelatine, such as are employed by fancy box-makers, are produced by pouring a solution of gelatine on to sheets of tin which have previously been treated with ox-gall to prevent its sticking. When the gelatine becomes dry the film is removed.

S. E. W.—We do not see that any advantage would accrue from your using arrowroot instead of starch for mounting your prints. Because the former is more expensive it does not follow that it is a better mountant, or that it would confer greater permanence on the prints.

A. H.—Your query shows that you are not, as you say you are, a constant reader of this Journal, otherwise you would not ask the question. Several articles have appeared on the subject very recently. We cannot do better than refer you to the back numbers for the past two or three months.

G. Wiltshire.—Decidedly the fault of the paper. Some drawing-paper can be used for photographic purposes, but not all. We advise you to procure several samples of different makes, and then by experiment determine which is the most suitable for your purpose. It is the only practical method to pursue.

T. Edge.—The most suitable paper for your purpose is that known as "*papier mineral.*" It is far freer from granularity than the sample you enclose. We are not quite sure where it is to be obtained, but we believe the Autotype Company supply it. Probably it may also be obtained at Messrs. Marion and Co.'s.

J. Burrell.—You will experience no difficulty in getting brown paper about five feet wide and any length you may require if you apply in the proper quarter. It is sold at carpet warehouses under the name of "carpet paper." We are not surprised that it is not kept in stock at ordinary stationery establishments.

E. Beveridge.—Any of the photomechanical processes will answer your purpose. If you elect to have either Woodburytype or stannotype it will require to be mounted like silver prints. But collotypes, or the "ink-photos," can be printed with a margin ready for binding up with the book. Your best plan will be to write for quotations to the different firms who supply such prints, stating exactly what you require, and, if possible, send a silver print as a further guide.

Experimentalist.—This correspondent complains that he cannot get the gelatinous ink to set in his stannotype moulds during the present hot weather. Our correspondent's experience is by no means exceptional, as the chief difficulty in working either the stannotype or Woodburytype process is experienced when the temperature is very high. The best advice we can offer is to work in the coolest part of the house, and to use a very strong gelatine for the ink. That which you have been using is quite unsuitable for the purpose at any part of the year, as it is far too soluble. Get a more insoluble kind and one that sets quickly, such as some of those of foreign make. Also, do not dissolve a large quantity of ink at a time, for you must bear in mind that the longer a solution of gelatine is kept melted the more its setting properties become destroyed.

Received.—"W.;" "S. R." In our next.

In Type.—Second portion of article on *Photomicrography at the Health Exhibition;* Mr. E. Dunmore's paper on *Silver Prints,* read at the last meeting of the Photographic Society of Great Britain; *Miscellaneous Subjects,* by Mr. W. H. Harrison; *On Choosing a Size for Carte and Cabinet Negatives,* by Mr. G. W. Webster; Lecture at the Royal Institution, &c., &c.

Photographic Club.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 16th inst., the subject for discussion will be the adjourned discussion—*On Focussing.* The Saturday afternoon outing will be held at Hadley Woods; train to Barnet Main Line Railway Station. Meeting afterwards at "Old Salisbury Arms," High Barnet.

No. 1263. Vol. XXXI.—JULY 18, 1884.

EMULSIONS IN GELATINE AND ALBUMEN.

The production of an albumen emulsion, for negative or positive purposes, has been one of the dreams of the experimentalist for years past, owing to the recognised beauty of the results attainable with albumen films. But, unfortunately, there are many serious obstacles in the way of the production of such an emulsion—that is, one in which albumen is the sole vehicle employed; and attention has, therefore, been turned more recently to the combination of albumen with some other substance—preferably gelatine. As a matter of course the results thus obtained differ very much from those we might expect from a pure albumen emulsion, in which the sensitive silver salt is *formed* in the presence of the albumen; but this latter condition forms the greatest and, we fear, an insuperable difficulty in the way of success.

When a film of dried, salted albumen is submitted to the action of a solution of silver nitrate, or other soluble silver salt, two chemical changes occur, in addition to that arising from the presence of the soluble chloride, bromide, and iodide. A portion of the albumen enters into combination with the silver, forming a complex substance to which the name of "albumenate of silver" has been given; and, secondly, the albumen film is coagulated and rendered insoluble, the result being a layer of extreme fineness and beauty, and capable of giving images of the most exquisite delicacy, possessing also, as well, great vigour and beauty of tone. The delicacy is due to the extremely-fine and structureless character of the coagulated albumen film, while the vigour and tone result from the presence of the organic silver compound.

Now, if to a salted albumen solution a solution of silver nitrate be added the same chemical changes occur, but with a widely-different mechanical result. The action of the silver is to entirely destroy the viscous nature of the solution by converting the soluble albumen into the insoluble form and into albumenate, both of which separates in a flocculent state from the watery portion of the mixture, and, together with inorganic silver salts, subside to the bottom of the vessel. To re-emulsify this flocculent mass comprises the problem which has hitherto baffled successful solution.

Again: if the albumen be mixed with some other viscous material, such as gelatine, it might be supposed that the latter would supply the place of the coagulated albumen, and retain it and the silver compounds in suspension in a sufficiently-fine state of division to form an emulsion. Such, however, is not the case; for so great is the tendency of albumen to "clot" that an extremely minute proportion of it, added to bromised gelatine, suffices to cause the formation of a curdy, granular deposit on the addition of silver nitrate, the silver bromide being entangled with the albumenous compound in the precipitate.

It is plain, then, if we desire to utilise albumen for emulsion purposes we must proceed in such a manner that it will never be brought into contact in solution with silver nitrate or any other substance capable of causing its coagulation; that, in fact, the silver haloids must be formed separately, and then added to the albumen solution Here some of the precipitation methods recommend themselves; and by their means, and with the expenditure of a considerable amount of care, beautifully fine emulsions can be made. But these do not answer our expectations on the score either of quality or convenience.

In the first place, the albumenate of silver is entirely absent, and, therefore, any advantage in colour or in brilliancy of image is lost. In the second, the emulsion is frequently difficult of application, the spreading and drying in a perfectly-even layer being next to impossible in our modern dark rooms. Lastly: without some special treatment after drying the film is soluble in cold water, more particularly when an alkali is present, as in the pyro.-ammonia developer. The latter defect might, however, be remedied without much trouble if the other two could be surmounted.

The presence of the necessary proportion of the albumenate might possibly be secured by its separate addition in solution in some suitable solvent; but it is extremely questionable whether the result would equal that obtained when it is formed in the ordinary way, as in a bath film. The coating of the plates, too, might be simplified by the introduction of suitable mechanical means; but we doubt, after all, whether the game would be considered worth the candle. It will be remembered by many of our readers that in the collodio-albumen process, in order to secure a film of perfect uniformity, the plate, after being coated with the iodised albumen, was placed upon a holder, which enabled it to be rotated before a clear, brisk fire until it became dry. If this were an operation requiring the greatest care when an *insensitive* material was employed and it could be performed in a full light, how much greater care would be required and how many fresh difficulties would be introduced into its practice in the dark room, and with an extremely sensitive emulsion!

If, however, the perfection of quality of the old collodio-albumen plate be not aimed at, but merely a finer and more delicate film with a moderate degree of sensitiveness, for such purposes we do not think our readers need despair of gaining their requirements. But it will have to be, as the title of this article suggests, by the employment of a combined gelatine and albumen emulsion. Plates of such a character are in the market, and give very fine results for transparency work, but we are not aware how they are prepared. Indeed, for all we know, they may be the result of sensitising a dried gelatino-albumen film in the bath, under which conditions the albumen would confer all its advantages.

For a gelatino-albumen emulsion which we have found to work very well in the few trials we have given it we may give the following brief sketch, reserving until next week the details and quantities. The silver bromide (or chloride) is formed by any of the methods of precipitation which enable it to be obtained in a state of sufficient fineness and free from all foreign matter. Burton's method is the one we prefer. The precipitate thus obtained is incorporated with a solution of gelatine at a temperature not exceeding 120° Fahr., and to this is then added a suitable quantity of liquid albumen, previously well beaten to a froth and allowed to subside.

When thoroughly mixed the emulsion may be filtered and treated in the ordinary manner, except that no alcohol must on any account be added, nor must it be raised to a higher temperature than 120° for fear of coagulation. Albumen does not commence to coagulate until about 150°, but it is well to keep on the safe side. Just sufficient gelatine is used to cause the films to set in reasonable time, the bulk of the vehicle being albumen, and the resulting films bright, fine, and hard to a degreee.

In our next issue we shall endeavour to give full details as to the working quantities, and hints on the mixing of the emulsion.

RELATION OF COLOURS IN PHOTOGRAPHS.

Whatever may be the advantage or otherwise of the addition of eosine or other colouring matter to the photographic film for the purpose of securing a truer transcript of colours into monochrome, it is clear that the subject is receiving considerably more attention on the continent than it is at home. This is evident from the fact that already there are several different claimants in the field for the invention. This, at least, should indicate that it is of some value in practice.

As will be seen from our last issue the subject has again been brought before the Berlin Association for the Cultivation of Photography and also the Photographic Society of Vienna; and, at the last meeting of the Photographic Society of France, M. A. Tailfer strongly protested against some of the Germans appropriating his invention "to the letter" and calling it their own. During the discussion which followed this protest it was proved that the credit of first introducing colouring matter into the sensitive film, for the purpose of obtaining a better translation of the colours of a picture in a photograph, is due to our own countryman, Major Waterhouse, Assistant-Surveyor-General of India. Surely all this interest would not be bestowed upon a subject if it were of no value.

That the matter receives but little attention in England is scarcely to be wondered at, seeing that the copying of works of art is practised here to such a limited extent compared with what it is throughout the continent generally. Indeed, we are told that many of the published copies of paintings in English galleries are really the production of continental photographers, who obtain permission, come over here, and do the work. We may here mention that an impression appears to prevail amongst certain English artists that works of art can be copied much better on the continent than at home, "because there they have a clearer light," and therefore a better result is obtained. In consequence of this idea many artists have actually sent their works abroad to be photographed, imagining (erroneously or otherwise) that they have obtained better results from so doing. Some artists, we know, positively refuse to have their works photographed under any circumstances whatever, owing to the way photography represents colours. On one occasion a Royal Academician remarked in our presence that he should be very sorry to have any of his pictures "libelled by photography."

Another reason why the addition of colouring matters to the film has received but little public attention here, compared with that it has had abroad, is that the copying of paintings in England is chiefly confined to a few professional photographers, who very rarely reveal the results of their experiments; while amateurs, as a rule, take no interest whatever in the matter. If they did, there is little doubt that considerable light would soon be thrown upon the subject.

From the manner in which photography, pure and simple, renders the colours of a painting it is not to be wondered at that artists do occasionally refuse to permit their work to be transcribed by its aid; hence the art-appreciating portion of the public are frequently debarred from obtaining copies of many pictures they would otherwise possess, simply because it would not prove sufficiently remunerative to have them engraved for publication. It is true there are several photographic engraving processes by which printing plates can be expeditiously and cheaply produced; but with them remains the unfortunate fact that, when they are obtained, they are but an ordinary *photographic* transcript of the original, and, unless such plates are elaborately re-worked by a skilled engraver, they possess but little value as pictures.

Much of the engraver's time, we happen to know, is sometimes saved by those who do this class of work employing a staff of skilful retouchers, who expend a considerable amount of work upon the negative in the first instance. Of course all this extra work adds naturally to the cost of production, and consequently enhances the price of the work when published. But if the simple expedient of adding eosine or similar colouring matter to the sensitive film will enable the difficulty of photographing colours in something like the proper relation to be overcome, we can, as we have on a former occasion said, foresee that an immense stride will have been made, and there is no question that the plan must prove of great value commercially. Hitherto there has always been a steady demand for good photographs of fine works of art, notwithstanding their shortcomings, as witness the large number imported from abroad and the prices they realise. This demand will, no doubt, increase considerably with improved quality, still further as the public become more assured that the copies they purchase are permanent; and most of the better class of copies of pictures are now printed by permanent processes.

If all that is claimed for eosine and similar colouring materials be borne out in practice, there will be no difficulty whatever in producing photo.-engraved plates that will require but little or no skilled work from the hand of the engraver. Hence copies of paintings may be issued as engravings and at the same time ensure a very liberal remuneration to the publisher, and that, too, from pictures which it would certainly not pay to have engraved by hand. One great advantage of photography and photo.-engraving is that the reproductions can be so quickly produced, while engraving by hand is a slow and tedious operation. The chief interest in a picture is frequently lost long before the prints can be issued, as several years are frequently necessary to engrave a plate from an elaborate picture; whereas, by some of the photo.-engraving processes, it can be done in little more than as many days.

Since the publication of Dr. Vogel's process (see pp. 344 and 360, *ante*) we have heard several photographers remark that it is not a practical one. With them we cannot agree. There are, it is true, some difficulties in the way of working, as we pointed out in our issue of the 6th ult., but they are by no means insurmountable. A considerable amount of time and money may profitably be expended upon the production of a perfect negative, from which, perhaps, hundreds of copies—at a publishing price of (say) half-a-guinea—may eventually be required.

Whatever may be the inconvenience attending the working of the process published by Dr. Vogel, they do not apply to that given by Herr Lohse—the one claimed by M. Tailfer as his. This simply consists of immersing an ordinary gelatino-bromide plate in a bath composed of water one hundred parts, eosine three parts, and ammonia ten parts. Whether plates thus simply treated will compare favourably with what is claimed for those by Dr. Vogel's more troublesome method can, of course, only be determined by actual experiment with the two processes. If they do, then the translation of colour into monochrome by photography will become very much simplified.

DETERIORATION OF GELATINE PLATES.

It is a well-recognised fact that under certain circumstances gelatino-bromide plates will retain their good qualities for several years; but it is, unfortunately, equally well acknowledged that some show indications of deterioration before they are many months old. One experienced maker has said in our hearing that he has recently had to destroy some hundreds of dozens of plates which, when freshly prepared, were all that could be desired as regards sensitiveness and cleanness of image, but, after having been packed in dozens and allowed to remain for a few months, they showed indubitable evidence of defects.

In recognition of this fact the subject was formally brought forward for discussion at the meeting of the London and Provincial Photographic Association last week, when several manufacturers were present and gave their experience on the subject. One speaker advanced the opinion that pressure, or "shearing stress," was the cause of a certain class of fogging; and in proof of this he submitted several plates which had been packed with a marginal or skeleton frame of thin card placed between each pair. Upon applying a developer to these plates, without any exposure to light having been given, a reduction of the silver took place all along the line of contact with the marginal mask, this reduction being most pronounced along the line corresponding with that edge of the card which was, by the action of the guillotine by which the cutting was effected, slightly the more raised of the two, and therefore more likely to exert a greater pressure.

Corroborative proof of this theory was adduced by the exhibition of plates upon which writing had been made by a blunt *stylus* upon the surface, precaution having been first taken to protect the gelatine film by interposing a sheet of paper between it and the writing instrument, in order to prevent any scratching, which, it was stated, would cause a reduction on the application of a developer. In the case adduced the writing upon the plate was quite visible.

All this was very plain as far as we have described it, but the evil did not stop there; for, extending inwards on the surface of the plate from the well-defined line of contact with the inner edges of the cardboard slip, could be plainly perceived a tolerably-broad line of fog which, from its greater density nearest the marginal slip, appeared to have its origin there, being vignetted inwards to the point of disappearance. Physical contact, *per se*, therefore, does not wholly account for the phenomenon described.

That the quality of the paper in which plates are packed, or which is interposed between each, had an important influence in preserving them was on the occasion referred to freely admitted by all. A well-known manufacturer present said that at one time he employed a specially-fine quality of cartridge-paper for this purpose, but was afterwards led to supersede it by a softer paper. Since that period he had never perceived any deterioration. But, on the otherhand, that chemical action induced by damp, rather than "shearing stress," was the cause of the deterioration seemed to be the opinion of others of the manufacturers present, including Mr. William Cobb and Mr. A. Cowan, the former of whom submitted for examination a sample of paper he had specially selected or prepared for the purposes of packing. It is a thin, crisp paper which looks as if it had to some very slight extent been impregnated with paraffine, wax, or their congeners. Another gentleman observed that the firm he represented had adopted a thin class of yellow paper—coloured, as was understood, by a chromium dye—for packing their plates, and it was believed to be a preventive of deterioration, for they had heard no complaints.

Whatever be the cause—whether "shearing stress" or moisture, even in a homœopathic degree, in the gelatine film itself or in the packing paper—the matter is a serious one; but the photographic public have the satisfaction of knowing that the makers of plates are fully alive to the necessities of the case. In due recognition of the moisture of the climate in England, they will omit no precautions not only to have both plates and packing-paper thoroughly desiccated, but to have them wrapped up in such a manner as to ensure their being retained in that essential condition.

SALEABLE PHOTOGRAPHS.

No one can pass along a street of shops without quickly noticing the important part that attractive photographs play in the wares vended in some, more particularly the stationers', establishments. The aggregate annual sales must form an immense sum. It is a matter of common knowledge how some particular photographs have, from no very explicable cause, seized the popular fancy, and rendered the fortunate possessor of the original negative or copyright a return upon his outlay thousandsfold. Although, however, it is not everyone who, by paying a hundred pounds, can count his gains by thousands, as did the purchaser of the copyright of the *Dirty Boy* statue, nor every one who possesses the judgment that guided the proprietors of a well-known company to expend a couple of thousand pounds to secure the sole right to photograph in the first International Exhibition, there can be no doubt that very much more money might be made than now is by utilising in a businesslike manner some of the stores of negatives of interesting, rare, beautiful, or otherwise attractive subjects that at present lie useless upon the shelves of the photographer.

To make a popular picture of a single negative or subject will be difficult—the more so that the wholesale channels for putting such works before the public are very restricted in character, and there may be an unwillingness to take up anything from a hitherto unknown artist; but, given a really attractive photograph—out of the common, well-executed, and likely to be admired by the public—and it is generally sure of ultimately working its way successfully.

One thing we may remind those of our readers who are unaccustomed to business of this kind: they must not expect to reap all the profit. When a picture has to be sold to a wholesale dealer, who again sells to the shopkeeper, each having to make his profit out of the article sold, it is evident that the producer of that picture must in the first instance receive a price very much less than that paid by the public; and if this fact be well borne in mind by an intending producer not accustomed to wholesale selling it will prevent considerable friction. The making and selling of the most artistic photograph possible to produce become, where quantities are in question, a mere matter of commerce, in which art takes no part. It may here be observed that in practice it would be found next to impossible to deal with the shopkeeper direct; a middleman must be employed.

One of the largest fields for the sale of these pictures is connected with the "Christmas card trade," which of late years has assumed such large proportions. Anyone owning negatives which he contemplates making use of in this way must be in the field long before the end of the year; indeed, we have no doubt that most of the wholesale orders for cards for next Christmas are already placed, and the bulk of them now ready for first delivery. This being so, we may be thought to be raising hopes that could not be fulfilled. We do not, however, think that it will be found so, and those photographers who feel inclined to look up their negatives need not be afraid of offering them even now, though we should make the suggestion not to offer, except at a likely period for a quick demand, subjects that could be readily imitated.

Besides the question of photographs sold in large quantity to the dealers, instances of which must be of comparatively infrequent occurrence, there are very many small circles which the photographer could find an interest in supplying. We do not refer to the sale of local views; that is a class of trade too well known and worked to need mention here. We speak more particularly of photographs specially interesting as studies, or likely to be attractive from some innate quality which might appeal to a local, though not important enough to put before a general, public. Every photographer must be his own judge as to what is likely to "take" in his neighbourhood. Our work ends in bringing the idea—possibly afresh—before him, and pointing out a novel field for enterprise; for in these days, when complaints of the unprofitable state of business are so rife, advantage should be taken of every available opening likely to lead to its increase.

One of our contributors has hit upon a happy idea which, summer time though it be, might, as we shall show, readily be imitated by numerous photographers.

One of the prettiest effects of which photography is capable is the reproduction of the marvellously-delicate and beautiful incrustations so commonly seen in winter time on the window-panes, when the frost has seized them and printed its delicate feathers in fleeting materials upon their surfaces. They are not all beautiful alike, and we have frequently noticed that the most attractive arrangements of the feathery scrolls are in such positions as offer the greatest difficulty to photographic attempts at reproducing them. The gentleman we alluded to [illegible], however, a very beautiful example by pointing his camera to the roof of his printing-room on an occasion when he was particularly struck by the appearance presented. The negative was put aside and forgotten, but some years afterwards he brought it out, printed a number of them and used them as Christmas cards, affixing a suitable motto. So attractive were they, he informs us, that if he had put them before the public in a commercial way he is sure he could have sold a very large number.

Now, with a backing of this sort, and a very pretty little scene or subject carefully printed in, somewhat after the fashion of the engravings, similarly executed, now so common in the illustrated serials, or treated in various other ways that will suggest themselves to the artistic mind, we make no doubt that a series of cards could be produced which would have a considerable sale.

We do not suggest to our readers who are not in the possession of such frost negatives to wait till winter comes; the time would be gone by for making a saleable quantity of pictures for the season. We would suggest that similar effects should be attempted by other means. It is stated that glass can be prepared for etching or for burning-in a pattern of water crystals by the following simple means:—Powder colour, such as is used for burning-in a white upon glass, is made into a thin, milky-looking liquid by mixing with a weak solution of gum arabic and painted upon a sheet of glass placed horizontally. The plate is then exposed to a freezing temperature, when the particles of water group themselves together into ice flowers or feathers, and draw the particles of colour lying between them also into similar shapes. The glass is now brought into a warmer room in which the water is allowed an opportunity of slowly evaporating, when at last nothing is left but the pigment, which can be burnt-in in a muffle. The photographer, however, will stop at the preliminary stage. He will not burn the pattern in; he will simply place it before his camera and take a negative under most favourable circumstances—not the least so being the power of placing a suitable backing behind the frost picture, the inability to do so under ordinary conditions often militating against the reproduction of many beautiful effects. With regard to the production of a low temperature there need be no difficulty whatever, as we have repeatedly given formulæ suitable for the purpose, many of which may be found in our ALMANAC.

We conclude, having thus described one particular class of picture capable of being made a means of profit, by pointing out that it is only one of many that might be with advantage taken up by an enterprising photographer.

THE death is announced from Paris of the Abbó Moigno, a leading spirit in scientific circles of a generation back. Commencing his scientific career as a contributor to various magazines of that class, in 1843 he established *Cosmos*, one of the leading reviews of its day; and this and its successsor *Les Mondes* became the media for the interchange of ideas of the early photographic experimentalists. The deceased was himself one of the earliest practical workers in photography, and his name was a very familiar one in connection with our art-science thirty or forty years ago. He died at the age of eighty-one.

PHOTOGRAPHERS' advertisements are sometimes very remarkable reading, and frequently go to strange lengths, but we never remember meeting with anything at all approaching the following, which we saw gravely stated in one of the daily papers as the advertisement of a photographer:—"In consequence of the daily increase of accidents by railway the public are earnestly requested to call at ——— and have their portraits taken, that some memento of departed friends may be left to sorrowing survivors."

GOVERNMENT aids photography in many ways, if not by direct "endowment of research," though, indeed, photography plays a [illegible] one, in a branch subsidised in this manner, [illegible] which much is to some persons as a red flag to [illegible] published statistics we learn that Government spends eight hundred and sixty pounds per annum in photographing our gaol-birds, and it used to spend a great deal more. Woolwich arsenal comes in for seven hundred and sixty pounds a-year, and a thousand pounds is spent under the auspices of the Science and Art Department for the photographing of art objects and the reproduction of pictures.

IN regard to the damage of photographic parcels in transit through post, as dwelt upon by us a week or two ago in a leading article, we may state that we have received a further communication from the Chief Secretary of the Post Office. We are sorry to say that so far our trouble seems to have been entirely thrown away, for we are left just where we started. The substance of the long letter received is simply a suggestion that still stronger wrappers should be used, and a further recommendation is given to send by parcel post as being in most cases a less risky mode. As to the hint we gave that information should be published of the places where the automatic dropping apparatus is in use so that special packing should be given, the Secretary points out that such information alone would not be of service. It cannot be doubted that the great amount of damage done to such parcels in transit is very great when a year's aggregate is examined, and we trust that others will follow our steps in appealing to head-quarters, this being the only way to obtain redress. We have written a further letter still to St. Martin's, repeating that the usual mode of packing is very strong, and pointing out that the official who first called to see us upon the subject informed us that there was a growing custom of sending small parcels-post packages by the mail bags. There for the present the matter rests.

APROPOS of the power of appreciating the minute shades of differences in colour, which was somewhat prominently brought forward at a few of the recent discussions on dark-room illumination, we may call attention to a second edition of the tests for colour-blindness which has just been published by Messrs. Churchill. The tests were prepared by Mr. Charles Roberts, F.R.C.S., for the Anthropometric Committee of the British Association, and he has added some valuable introductory remarks to it. It is a singular thing that many persons colour-blind to one colour arrive at mature years without a suspicion of their defect, and it often happens that the first discovery is attended with some amount of annoyance. We had the privilege of knowing a gentleman of great culture who studied painting with the intention of following it up as a profession, and he had attained manhood and pursued his studies for many years before he became aware that he was colour-blind. A very clever and celebrated provincial photographer is to our knowledge quite colour-blind, and we have been informed by a well-known contributor to this Journal that there is a marked difference between the power of colour perception of his eyes. With instances like this before us it cannot be wondered at that such apparently contradictory opinions should be held upon the question. We have no doubt that many photographers are slightly or considerably colour-blind. The Rev. T. A. Preston has made about three thousand observations upon the subject, and he finds that two and a-half per cent. of the boys he has examined are colour-blind, not to speak of a very large proportion who are near-sighted and long-sighted.

IN some respects it may be regretted that the Copyright Bill has been withdrawn; but it is to be hoped that it may be re-introduced with improvements in another session, for, as it stood, it was open to many amendments. That a Copyright Bill of a very stringent character is desirable we believe. The larceny of the results of a man's brains, be it pictorially or verbally expressed, is to our mind as great a theft as the purloining of a watch or purse, and it is to be hoped that when a Bill, as nearly final as can be expected, is passed it may be a real help to photographers.

THERE is one very large class of persons whom, by reason of their crass ignorance, it would be very difficult either to touch by law or to teach the moral right that exists in the product of a man's intellect, and yet occasions must arise at times when the photographer's patience and forbearance are greatly tried. A case has just been brought under our notice that fully exemplifies what we say. A well-known photographer had a sitter who had never hitherto had a good portrait, and he took especial pains that the picture he produced should prevent him being able to say so again. The picture (*a carte*) was a success, and some little time afterwards a question was asked as to the price for enlarging it to cabinet size. The price was stated, and for a while the matter lay in abeyance. The photographer's surprise can be imagined when, a month or two later, his sitter calmly brought him an unmounted enlargement "to be fastened upon card;" it had been sent to America, enlarged, and returned to this country! Our readers may guess at the answer the photographer gave to this amazingly-cool request, which was not impertinent, simply because of its thoughtless ignorance.

STILL another piracy case. An art exhibition, in connection with a *conversazione*, was being arranged upon the walls, and the friends of the promoters had assisted by sending in photographs. Two large photographs—not from engravings but from wretched foreign lithographs—of two well-known (and much pirated) pictures, the *Emigrant's Return* and the companion picture, had been sent in, when their piratical character was distinctly pointed out to the committee-man. To use a sporting phrase he, however, never "turned a hair." "Oh! they will do to fill up," he said, and up the pictures went to a post of honour! When such an event could happen under the sanction of a committee expressly constituted for the furtherance of art and art teaching, how is it possible to grumble at the piracy or the attempts at it sanctioned and encouraged by the general public?

A FEW FURTHER NOTES ON STANNOTYPE, BY THE INVENTOR.

THE able series of articles on stannotype, which lately appeared in your journal, have been so exhaustive that I am afraid I cannot add much to them, except in calling attention to small matters of detail which have come under my notice from time to time during the past year or two.

Failures, as a rule, result from some trifling cause which, when known, may easily be obviated. How often have I been called on to give the reason of some defect or other, and on explaining the cause have had for reply—"How stupid it was of me not to think of it!" Everything, however simple, requires a certain amount of experience or apprenticeship. It is in trifles that thorough success must be sought for. Just as I sat down to write this article I received the number of THE BRITISH JOURNAL OF PHOTOGRAPHY for July 11th, and, to begin with, I cannot do better than notice your answer to a correspondent.

Alluding, as it does, to one of the principal causes of failure (which, by the way, applies mostly to all processes where gelatine is concerned), your correspondent, "Experimentalist," complains of his ink not setting. Unless he is possessed of a cool cellar or underground room his cook would tell him that he could not have jelly for his dinner. My own experience during the last week will, doubtless, be of use to him. The temperature of the printing-room rose to 86°, and printing operations were brought to a standstill, the ink, although strong in gelatine, keeping liquid in the bottle. However, on removing the presses, ink, &c., to the basement, where the temperature was under 70°,* all went on smoothly again.

Prints *can* be obtained at high temperature by a long process of cooling by the iron body of the press; but after a time this becomes too warm to cause the gelatine to set, and gives rise to a great annoyance, which, being an important point in working, I may here mention, as it applies to all prints taken too soon from the mould.

The paper carrying the print, on being removed from the mould (owing to the gelatine not having set thoroughly), leaves some of the darkest parts (where there is most gelatine) in the hollows of the mould, and if these are rubbed off with the same flannel that has been used to grease the mould the trouble is increased tenfold. Although the mould may appear clean and bright the next proof will stick worse than the first, owing to the fact that a sort of emulsion has been formed between the gelatine and the grease, which entirely prevents the removal of future prints. The only remedy is, after removing all superfluous gelatine, to wash the mould with clean warm water and grease afresh.

I have called attention to this particularly, as it is a fault likely to occur at any time, but especially in hot weather. Everyone cannot afford the luxury of ice; otherwise the difficulty of hot weather printing is easily removed. I remember some years ago, at the last great Paris Exhibition, going into an *annexe*—a handsome building of one storey, in the grounds—where M. Vidal was working the Woodbury process. The room was crowded and the heat excessive from the combination of crowd and the broiling sun shining on the building. From old experience I thought to myself that the crowd would certainly go away disappointed if they expected to see anything in the printing line where gelatine was concerned. What was my astonishment to see a middle-aged woman with a turn-table before her, quietly stripping the prints from the moulds at intervals of five or six minutes! The air was suffocating, and I was glad to get out. My friend M. Vidal afterwards explained to me that under each press there was a tray containing ice, so arranged that it could be re-charged when melted.

This reminiscence of hot weather in connection with Woodbury printing has called to my recollection another case further back in the annals of time. The late Emperor of the French, who took a great interest in all scientific matters, happened to visit one of the exhibitions, and was so pleased with the Woodbury process that, not having the time to devote to everything at once, he made a special appointment to come privately with the Empress, so as to have a practical demonstration all to themselves. The day was hot and the gelatine would not set, even after five to ten minutes in the press. What was to be done? A few pounds of ice were procured and laid on the backs of the presses, and in the course of half-an-hour, by the time their Majesties arrived, all was going smoothly. What would he have thought of the process he had admired from description if the *practical* results had been similar to those which once occurred at a lecture where, the room being heated by the over-crowding of a numerous audience, the print had come away leaving half the gelatine in the mould? Only one of ready wit could have explained it as a *double success*, as the lecturer did on that occasion.

I can, therefore, affirm that with a suitable room, which can be found in almost every house, there should be no difficulty in working either the Woodburytype or stannotype processes, provided a suitable gelatine be used; and such is now to be had.

Referring again to the article, or rather answer, to "Experimentalist:" I come to a point on which, from long experience, I must differ slightly from the Editors; that is, that "the longer a solution of gelatine is kept melted the more its setting properties become destroyed." Now, on the contrary, my experience is that to keep a mixture of gelatine, with or without the addition of any other matter, for any length of time it is necessary that it *should be melted* every day, of course not allowing it to rise to too high a temperature. I cannot do better than give an illustration from a circumstance which lately occurred. Some thick flakes of gelatine in the old glue form, and of a high setting quality, were put to soak in water on the Saturday. On the Monday morning following they were found all soft and rotten on the surface, and, on melting, the solution was found to have lost all its setting properties. Now this same sample of gelatine in solution has been in use for several weeks during the whole of the late hot weather without any change, but has been kept melted every day. Soft gelatines—such as Nelson's amber—on the contrary, lose their setting properties by too much melting. The above fact, which long experience enables me to vouch for, seems at variance with existing ideas, though I must say that it is a verification of the old proverb of the proof of the pudding being in the (h)eating.

A great many defects arise from want of care in the storing and handling of the paper used in printing. Any crease formed in it will make a white mark wherever the paper is dented, and if left in a room where dust can fall on it every speck of the same will cause a white spot in the print.

The chief point in obtaining a good stannotype printing mould is to get a positive that has been rightly exposed—just such a one as will, when laid on paper, show the right amount of detail. In the Lambertype process each print had to be exposed separately to light; but for the purposes of stannotype printing we have only to produce one such print, as obtained by the process named, to enable us to produce many thousand stannotype prints. As the positive is, so will your prints be. If over-exposed, the resulting prints will all have the same over-exposed look. Such a positive as is used for enlarging is not the slightest use for stannotype.

In drying the printing moulds by the aid of spirit make allowance for the time this has been used. When quite fresh half-an-hour to an hour will be long enough; but if the spirit have been used some time it will have taken up a good deal of water, and the reliefs should, therefore, be allowed to remain a proportionately longer time.

During very dry, hot weather—such as we have lately experienced—the gelatine relief, if kept open to the air, may crack and leave the glass; but this cannot occur when once covered with the tinfoil coating. It is very rarely, indeed, that our atmosphere is so dry as to cause this, but in drier climates it is advisable to increase the amount of glycerine in the tissue.

* During the short duration of hot weather that we experience in this country it is advisable to do as the Woodbury Printing Company were in the habit of doing—that is, commencing printing operations at five o'clock in the morning, leaving off at noon, by which time the metal of the presses becomes warmed through.

In applying the tinfoil to the mould care should be taken that the india-rubber solution is thoroughly set; as, if not, and any were squeezed out on to the india-rubber rollers, it might soften their surface and so cause them to become tacky, making the foil stick to the rollers. In smoothing the foil on the sheet of plate glass see that the latter is perfectly clean, as any grit or dirt would cause holes in the foil.

In remelting the surplus ink that has run into the gutters of the press, and the scrapings from the prints, do not forget, on remelting, that owing to the evaporation the ink will have become denser, and will therefore require the addition of water. Many people have experienced some little difficulty in the gelatine leaving the glass during the process of development. This is due to several causes, but mainly by using too opaque a mask. The paper used should be such as will allow the light to act very lightly on the film. An abrupt transition from the thick border to plain glass is apt to produce this, more especially if the tissue, by keeping too long, has become slightly insoluble. In the making of the positive, the film being much thinner, blacker paper may be used as a mask; in fact, where a negative has to be duplicated or quadrupled a perfectly opaque mask is a necessity.

In conclusion: I cannot do better just now than call the attention of your readers interested in stannotype to the leading article in a late number of the Journal, entitled *Keeping Cool*, and say that I shall at all times be glad to answer any queries on the subject through the medium of the Journal. WALTER B. WOODBURY.

OXYHYDROGEN EXPLOSIONS.

I do not quite understand the drift of Mr. Houston's communication. So far as I do understand it, he (1) wishes to know how far I am acquainted with, or believe in, "dust explosions" generally; and (2) meets whatever I may have heard concerning explosions in the United States, by what he has *not* heard.

As to the first point: I happen to be pretty fully acquainted with the subject, and with Professor Peck's experimental lecture upon it, which was delivered in May, 1878, at the special request of the millers of Minneapolis, U.S. Just about three months ago I myself repeated two of those experiments in a familiar lecturette upon some phenomena of combustion to a small society of working men, using for the purpose flour and the spores of lycopodium. I know how, in the United States, such explosions have taken place in many flour-mills, in a manure factory, a confectionery establishment, a brimstone-mill, and probably in some others; while in this country the chief examples are flour-mills, breweries (Messrs. Allsopp had an explosion in 1877) and coal-mines. I said clearly that it was perfectly easy to produce *purposely* a dust-explosion in a gas-bag.

But these cases do not touch the question in point. In all of them we have dust known to be explosive constantly produced; we have more or less constant production by attrition of ignited particles, or (often) naked lights introduced into the known explosive dust; and we have a known long list of casualties. I am perfectly open to conviction; but I have been utterly unable to learn that any gas-bag explosion recorded has ever been even probably traced to any such cause; and surely those who imply that bags are "unsafe" on that ground, ought at least to be able to point to some one case where such a cause at least seems to have operated. At present I believe this particular danger to be a pure myth; but we are all open to any evidence on the subject.

As to the other point: I have already cited an explosion of a bottle at the Royal Institution some years ago, with the very uncomfortable symptom of *the iron being burnt*. In regard to the United States: from the papers I see, my impression is that, owing to the extreme absorption in politics, ordinary "accidents and offences" are *not* reported there with anything like the completeness of English newspapers; and that (with one or two exceptions) the technical journals are poor by comparison in real intelligence of any kind. I have been told what I stated by persons who have been personally acquainted with what they alleged; but, not dreaming of the fact being challenged, I never noted special incidents. One case, however, should be as good as many in reply to this peculiar argument; and it is only a few weeks since Mr. R. A. Proctor stated, in *Knowledge*, how discomposed he had felt, when assisted at one of his lectures by a bottle operator, by both operator and apparatus—so much so, that he "made a change." He further relates that, not very long after, that operator's apparatus exploded, with the loss of two lives. That was my reason for specially mentioning Mr. Proctor's name.

I have nothing to say to any man's "preference" for bottles. I shall "prefer" them when the stated conditions are fulfilled. But others who *cannot* use them without expense or inconvenience ought not to be condemned without reason shown and some shadow of evidence. I wrote in their defence—not to attack bottles. And I may say, in conclusion, that to bring about their general use one of the most necessary things is to *reduce the price of gas.* In America it is ridiculously cheaper than 8d. per foot. The chemicals cost 2d. per foot here, and I think 4d. per foot and the hire of the bottle should pay. It might not pay at first; but a wholesale demand would put another face on the compressed-gas business altogether. It is long since I heard, but I think in America the wholesale price then was about six cents, and the retail about seven and a-half cents. If they can do it there, why cannot it be done here? LEWIS WRIGHT.

PHOTOGRAPHIC INDUSTRIES.

A WEST-END STUDIO.

If the photographers of the metropolis were called upon to declare by vote who, in their estimation, was the member of their fraternity possessing the greatest amount of ingenuity in things appertaining to the mechanics of our art-science, they would without a single dissentient voice proclaim the name of Alexander Cowan. While circumstances have conspired for over twenty years to associate this gentleman with the establishment so long known as that of Hills and Saunders, "photographers by appointment to the Queen," Porchester Terrace, Bayswater, W., nature has certainly designed him for an inventor.

There are two classes of inventors: the one thinks the matter out, conceives the adaptation of means to an end, completes the general principles in his head, but is unable to prosecute the matter any farther. Mr. Cowan does all this, but, in addition, possesses the important faculty of being able to carry all his ideas into practical execution. This statement will receive prompt confirmation from all who attend the meetings of the various metropolitan photographic clubs, associations, and societies—of all who have had opportunities of inspecting the useful inventions he has from time to time submitted for examination, while admiring the fine fitting and beautiful workmanship of the same. But we would err were we to leave an impression that the fertility of invention displayed by this gentleman was confined to what are termed the mere mechanics of our art; for, on the contrary, in both the chemical and what we may designate as the other physical aspects of photography he has made his name well known.

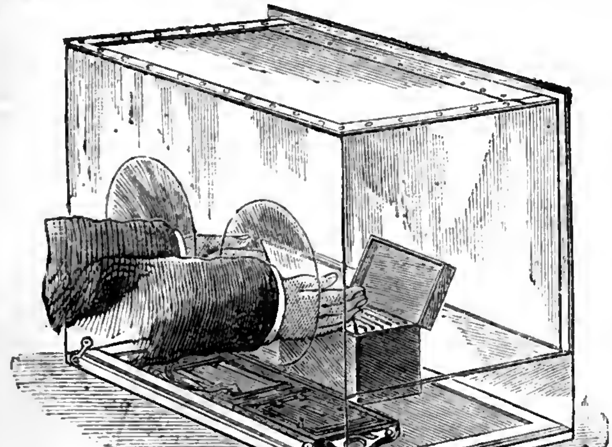
Remarking that on the occasion of a former visit (some years since) Mr. Cowan made his camera exposures through the medium of an electric wire, which extended from end to end near to the roof of the studio, our first glance was an upward one, with a view of ascertaining if this remained *in statu quo.* We found that the electrical conditions had undergone a change, and that the camera contained them all within itself, or, more correctly, within the stand. Glancing downwards we perceived as a conspicuous and somewhat ornamental appendage to the camera stand what purported to be a large electro-magnet, but which, when the top was removed by Mr. Cowan, revealed the fact that it was in reality a four-cell constant battery, two elements being ensconsed in each limb of the pseudo magnet. The exposing shutter being inside of the camera, it will easily be understood that the sitter is not necessarily aware of the moment at which the exposure is made.

But in the matter of exposures Mr. Cowan prefers "two strings to his bow;" hence the same camera has also attached to it a pneumatic apparatus, the exposing action of which is this gentleman's own invention. By its means the exposure may be either extremely rapid or prolonged at will. There are two shutters—one above the other. They are actuated by gravity, but each is held in check by an appliance similar to the pallets of a clock movement. When ready for exposure the lower of the shutters stands before—or, as in this case, behind—the lens. By pressing the pneumatic ball this lower shutter falls without the slightest jerk, being caught between two springs at the bottom. But the action by which it is released throws the upper limb of the pallets into a notch in the side of the upper shutter, which is thus held in its place until the pressure is removed from the ball, when it, too, drops and cuts off all passage of the light. A momentary pinch of the ball causes an exposure as quick as may be obtained with many of the so-called instantaneous shutters.

Conversing with Mr. Cowan on the subject of transferring plates from the plate-box to the dark slides when at a distance from a properly-darkened room, we were shown the portable changing-box he had introduced some time ago. It forms, when closed up, a packing-case, in which is stored away a camera for 12 × 10 plates, grooved boxes containing ample supplies of plates, together with dark slides and all the "belongings" of the camera. When the contents are removed the box is erected by means of appropriate stretchers. It is then found that the body consists of four thicknesses of black calico. There are two sleeves through which the hands are inserted. The plate-box and dark slide having previously been placed on the bottom, for which special facilities are afforded, the hands are then inserted and all the manipulations effected by feeling. By the exercise of care and a little system any one who makes trial of the method of changing plates on any table before him will be surprised to find with what ease and certainty this may be done when the eyes are closed or the room rendered totally dark. The annexed diagram gives a good idea, not only of the changing-box, but of the way by which the plates are transferred by touch to the slides, and from them back again to the plate box.

Descending from the studio we passed into a garden through the basement story, in which are situated the laboratories, enlarging-room, and a well-appointed amateur mechanics' workshop fitted with carpenter's bench, turning-lathe, circular saws, and quite a number of other mechanical appliances. At the foot of the garden is the house devoted to the preparation of dry plates.

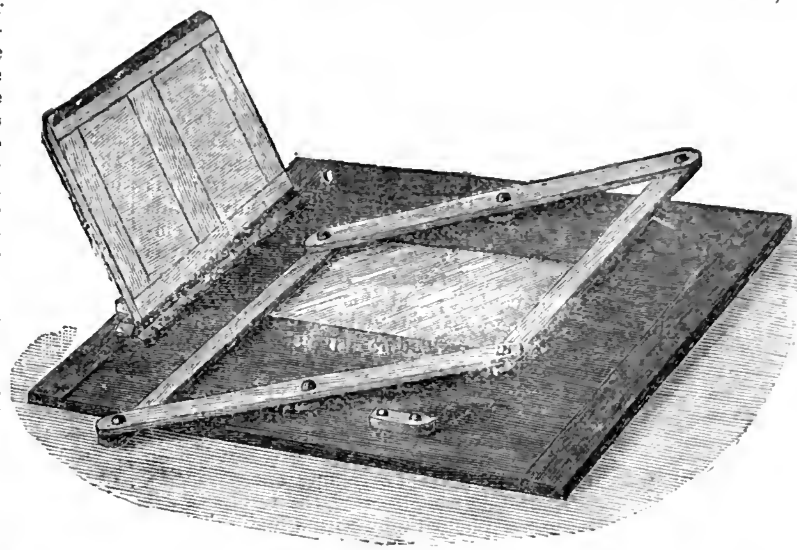
Here we saw a machine for cleaning the emulsion off the back of the plates. It is very ingenious, but we fear it could not be described without the aid of elaborate drawings, although it is simple enough in itself. A plate having been seized by the pneumatic



holder is first coated with the emulsion, and, without relaxing the grasp upon the holder, is held for a moment on the top of two large vice-like jaws, which are padded, and which by the action of a lever, operated by the toe of the person coating, immediately opens, and thus removes any gelatine which might have got on the back. A ratchet actuated by automatic means effects a change of the rubbing-cloth, and brings a fresh portion of the surface into action with each plate.

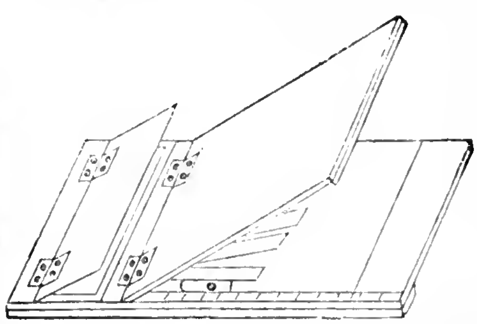
The drying-room is ventilated by a species of calorigen, by which the moist air is drawn off and conveyed to the outside, an influx of dry air taking its place. The time required for the complete desiccation of a plate under ordinary atmospheric conditions may be said to be from six o'clock in the evening till ten o'clock the next morning.

In the drying-room are several cutting-boards. Various means have been contrived to effect the division of a plate into two parts absolutely equal to each other. It is questionable if anything *can* equal or even approach that of Mr. Cowan's in simplicity and absolute certainty of action. On a cutting-board of any required dimensions are erected four long slips of wood pivoted at the corners, the two side pieces being also pivoted to the board at their centres. It follows that, no matter how this framework is moved from side to side, its

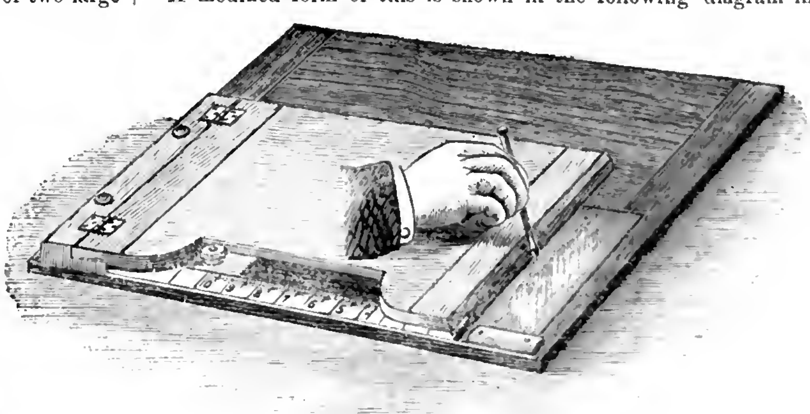


ends will always preserve parallelism and equidistance from the centre. A glass plate may be laid on the cutting-board "anyhow," when by a lateral motion of one end of the frame it will be pushed into an unerring central position by the end bars, after which a second board having a straight face is folded down upon the plate and the cutting diamond applied to the plate, which is thus bisected. This cutting-board is shown in the accompanying diagram, in which a plate is shown centered in a state of parallelism. The bars being then brought square with the board (to effect which a check piece is employed), the ruler or straight-edge shown at the left end is folded down as the guide for the diamond.

Another convenient form of cutting-board we saw in action is that which was described in our ALMANAC for 1879—its purpose, unlike that of the one just described, being to permit of a large plate being cut into smaller ones of definite dimensions. A series of rules of wood of various lengths can be folded out upon the cutting-board, and the end of the plate brought up against any one of them. The hinged flap is then lowered down till a sharp fillet at the end comes to the film and holds the plate securely, when the diamond is drawn across its outer edge.



A modified form of this is shown in the following diagram in



which the stop is made movable; and a still more complete form is one containing two movable stops on each side of the board, enabling one to accurately gauge any odd sized plate, and at once adapt the board to cut *exactly* the same proportion without resorting to measurement in inches.

We have alluded to the enlarging-room. There is one feature in the fitting of this which is worthy of special notice. It is this: that the basement of the travelling easel upon which the plate is supported is attached to the wall instead of resting upon the floor. This imparts a degree of firmness and solidity quite impossible to be obtained when the floor forms the means of support. The axis of this enlarging apparatus is horizontal, the light being directed through the negative and lens by a mirror placed outside, which is susceptible of being adjusted to any desired extent. Only in this department of the establishment is the wet collodion process employed. The method adopted in ordinary cases of enlargement is as follows:—From the small negative a transparency is produced on a gelatino-chloride plate by contact; and this transparency when placed at the mirror-end of the apparatus yields a negative of any dimensions up to twenty-six inches. The negative thus obtained—on wet collodion, as we have said—is employed in the production of a print in carbon. For enlarging Mr. Cowan employs a portrait combination lens of large diameter—large, at anyrate, as compared with those so frequently employed for a similar purpose.

From the various communications publicly made by Mr. Cowan respecting gelatino-chloride as a means of obtaining transparencies, it will be readily understood that we witnessed the results of his investigations in this branch of photography with a high degree of interest. We may here recal a description we gave of a frame of transparencies he showed at the annual Photographic Exhibition of last year. It contained twenty lantern slides, all of them being the same as regards subject, and all gelatine emulsion plates prepared alike, yet not two of the twenty were of the same colour. The tones ran through every shade and gradation from a very decided red on to a cold black, passing from red to bistre, sepia, the various shades of browns, purples, and blacks—blue-black, brown-black, and jet-black. And yet, as we have said, the plates were all prepared alike, the special tone being obtained by modifying the developer. We saw several transparencies made in the modified developers. For cold tones, citrate and oxalate of potash mixed with sulphate of iron were employed. Warm tones were obtained by citric acid and carbonate of ammonia in various proportions (together with iron), the addition of chloride of sodium imparting a specially-rich, warm tone.

From the preparation to the packing of dry-plates the transition is natural. Of all the mechanical inventions of Mr. Cowan probably his plate-packing machine is that which will elicit the highest admiration, on account of the happy adaptation of means to a particular end. We shall not attempt to describe it, but will merely say that a plain strip of paper, which is hereafter to be folded into a zigzag form and inserted between the plates, is placed upon the bed of the machine, a plate being then superimposed. By a motion of a side piece the paper is folded and another plate ready to be laid down, followed in turn by a similar action. These alternations are repeated till the entire dozen plates are conveyed to the bed of the machine, when all are found admirably piled on top of each other with an indented slip of paper between each, the whole being ready to be placed in the packing-box in which plates are usually sent out.

We would needlessly prolong this article were we to speak of numerous mechanical inventions of a minor character which owe their existence to Mr. Cowan; but among these we may allude to, without describing, his lantern transparency printing-frame and his lantern-slide carrier, a description of which was given in a recent number of THE BRITISH JOURNAL OF PHOTOGRAPHY.

In connection with several of the productions we have mentioned Mr. Cowan has allied himself with Messrs. Marion and Co. as distributors—a fact of which the readers of our advertising columns are well aware.

SELF-REGISTERING HYGROMETER.

WE have often pointed out the many uses to which a hygrometer can be put in photographic operations. Such work in gelatine plate or tissue drying being naturally governed to a great extent by the amount of water present in the atmosphere, a ready means of ascertaining that amount will be of considerable use in arranging the most favourable conditions.

Doubly useful, therefore, would be an instrument which informs us of the hygrometric state of the atmosphere—not only at the time of making an observation, but also for the whole period intervening since the previous observation. Such a self-registering instrument would be a valuable check upon the state of films and tissue after being placed in the drying-rooms, and would show at once whether any unevenness might be put down to atmospheric causes, or whether others should be sought.

According to our contemporary, *La Nature*, MM. Richard Frères, well known as constructors of self-registering barometers and thermometers, have turned their attention to hygrometers, and, after some amount of success with gold-beaters' skin as the sensitive agent, have discovered an animal substance never hitherto tried for the purposes of hygrometry, and possessing remarkable qualities of permanence and exactitude.

This material is unprepared cow's horn, which, cut in bands about two feet long, a third of an inch wide, and one-eightieth of an inch thick, have enabled these gentlemen to construct an instrument answering every scientific requirement. In it the tension of the band of horn is used in connection with a small lever working direct a needle or style. This style carries at its extremity a pen similar to that used with the now-familiar self-registering barometer. There is thus obtained in ink a diagram of the hygrometric state of the air upon a piece of paper rolled round a cylinder revolving once in a week by means of a clockwork attachment.

The instrument is graduated by comparison with a clock working in atmospheres artificially created with extremes of moisture and dryness, these points being taken by means of a Regnault's condensation hygrometer perfected by Alluard. It is easy to understand that an instrument so regulated gives the absolute hygrometric state of the atmosphere, thus avoiding the inconvenience attaching to the indications of other instruments in which animal membrane is employed, they, as is well known, requiring comparison with a table of constants to reduce their indications to those of absolute measure of the moisture present.

It is stated that several instruments constructed on the new principle have been working and under examination for two years, frequent comparisons with the condensation hygrometer having been made. The maximum error in one rare instance was five per cent., but usually it did not attain one per cent.

SILVER PRINTS.

[A communication to the Photographic Society of Great Britain.]

THE paramount importance of ensuring permanency in our silver prints has induced me to put together a few notes, as supplementary to the interesting paper on *Fading* read by Mr. John Spiller at the last meeting of this Society. It will be well, in the first place, to decide upon the standard we are to set up as to permanency. Will a picture on paper, an engraving in fatty ink, *e.g.*, supply it? or are we to put silver prints in competition with flint or wrought-iron, expect them to resist boiling, or even soaking, in strong solutions of hyposulphite of soda without injury? The phrase "permanent" is very elastic, and at best is but an expression used to indicate durability, not by any means indestructibility; but, for all intents and purposes, if a silver print will remain good as when made if treated as most pictures of any value are treated, hung on the wall or placed in the portfolio, it in my opinion fulfils all the requirements that can reasonably be expected of it. What more need we seek? Many silver prints produced in the early days are as good and perfect now as they were then, no especial care having been taken of them; and this in not only one or two isolated instances, but in many.

Now it is an axiom that anything that can be repeated must be subject to certain rules, or the reproduction could not take place; therefore it is absolutely certain that, if we knew the precise conditions attending the manufacture of these particular prints, by following the same routine exactly we should risk no failure or have fading prints—in fact, permanency would be assured. As an aid to permanence, many years ago Mr. Spiller suggested the use of ammonia carbonate in the hyposulphite bath as assisting the solution of the unstable silver salts formed in the paper; at that time I was using carbonate of soda, but with a different intent. I had been complaining of the reducing action of the hyposulphite solution on my proofs to a brother photographer, who attributed it, as many faults were attributed in those days, to acid hypo. If this were the case, I thought the addition of a little alkali might remedy it, be a reasonable precaution, or, at any rate, do no harm. I made the addition of sodium carbonate to the hyposulphite bath, with a decided improvement in the results, for which I substituted the ammonium-carbonate after reading Mr. Spiller's remarks thereupon, and continued its use afterwards. About nine years ago I adopted it as an improvement at Mr. Bedford's works, and after using a hundredweight or so of the ammonia-carbonate discontinued it, finding that a whitish deposit was formed on the surface of the prints, which, though very slight, still injured their appearance as the light fell upon them at certain angles. This deposit was loosely attached, and a rub with a soft rag easily removed it; but the trouble incurred was considered to more than overbalance the advantages gained. The use of ammonia was in consequence discontinued.

We will now, for the present, leave the matter of permanency to consider of what in reality a silver print consists; a definite understanding on this point is very material to any argument that may result thereupon. To get an idea of this it will be necessary to sketch out the process of silver printing *ab initio*, taking the paper itself for a starting-point. Photographic paper is, and has been from the first, almost exclusively supplied from foreign mills, the words "Rives" and "Saxo" being almost synonymous with photographic paper. This, the foundation of our prints, seems somewhat inferior to earlier makes. The inferiority is not in appearance or texture, but in the increased difficulty of causing it when sensitised to retain its whiteness without extraordinary precautions that were unnecessary at an earlier date; an hour or two in warm weather is sufficient length of time to gain a decided yellowness, when formerly, under similar conditions, the colour would be pure and white for a day or two. I am not sufficiently acquainted with the manufacture to suggest the reason; I can only record the fact.

This seems to be the only portion of a silver print that is *actually* beyond the control of the photographer, if we except metal spots, which in the Saxe make of paper seem more numerous now than formerly; these are, however, local troubles, and have no effect on the permanence of the print, and are probably due to particles of metal abraded from the machinery during the process of manufacture, or hot-pressing afterwards, or rolling.

Albumenising is the next process, which is now so seldom done by photographers that it is practically out of their control, although they could do it if they so willed; and much depends upon it. This should consist of pure fresh egg albumen mixed with a definite quantity of some chloride, and applied to the surface of the paper, *secundum artem*. Ammonium-chloride is, I believe, generally preferred as giving a better colour than other salts. In addition to this, some makers add other substances for the purpose of increasing the gloss, or to improve the keeping qualities of the paper. Citric and acetic acid are added, more especially during warm summer weather. If albumen from blood or gelatine is used, mixed with or in lieu of pure egg albumen, imperfect results are more likely to occur, and the proofs on such paper are wanting in richness and evenness of colour, acting themselves as a caution against the use of that particular sample of paper. Stale albumen is well known to give a higher gloss, but its offensive smell and doubtful qualities as a rule cause such paper to be rejected. Prints upon it have, however, been found to remain bright and pure, as with fresh albumen, and to show no signs after the lapse of years either of fading or yellowness. The paper, being albumenised and dried, is now floated on a bath of silver nitrate, of a strength of between sixty and seventy grains per ounce. The strength is, however, somewhat regulated by the amount of salt in the albumen, care being taken to have a *considerable* excess of silver salt. A large amount of uncombined silver nitrate facilitates both printing and toning. The prints are richer in colour, and tone more readily, and, to my thinking, if strong baths are used, more permanent. The paper thus prepared is dried and exposed to the light under a negative to make a positive print. The resulting action has been, and still continues to be, somewhat a matter of conjecture, but not less important on that account. A number of complex changes undoubtedly take place, and, according to various careful experimenters, the principal change is that the chloride of silver is reduced to the form of a subsalt and a red substance, which is left on decomposing the subsalt by hyposulphite of soda in the act of fixing. This is the theory set forth in *Hardwich's Chemistry*. It is, however, somewhat incomplete, and will not account for the varying results continually brought before us; therefore, again adverting to the axiom that anything to be repeated must be subject to some definite rule, we undoubtedly require further knowledge of this particular part of the process. What, for instance, is the "red substance" that forms an important part of the photographic image? When silver nitrate is applied to organic matter darkening of the substance takes place, not only in the light, but in the dark, the silver being reduced to a metallic state, light greatly accelerating the change which bears some relation to the intensity of the light acting upon it. Suppose, in addition to the subsalt theory already advanced, that the silver became reduced partly to a metallic state, and partly to a state of oxide, nitric acid being liberated. Many years ago M. Devill found, that by acting on silver nitrate with chlorine, dry nitric acid was formed. Is it unreasonable to suppose that free nitric acid being liberated by the reduction of the silver nitrate to a metallic state, which, in its turn, is partly deoxidised by the light, the oxygen attacking the reduced silver, nitrous acid escaping and acting on the organic matter with which it is in such intimate contact that xanthoproteic acid results, which we know is of a deep yellow colour, and darkened by alkalies, this may form the basis of the "red surface" to which Hardwich refers. The preservative effects of a carbonated paper on sensitised paper is well known, and the effect is especially noticeable when placed in the printing-frames, at the back, and in close contact with the sensitive paper during the operation of printing. Its preservative qualities are attributed to this power of neutralising any liberated acid. In connection with this, I may remark that the addition of a considerable quantity of nitric acid to the silver bath somewhat expedites the printing, and that the ready sensitised and some samples of unsensitised paper contain a very large amount of free acid. The result tends, in all instances, to more rapid impressions. The silver print seems to principally consist of coloured organic matter, oxide of and metallic silver, previous to toning, which inclines me to the opinion that a silver print consists of *two entirely distinct images—one an organic and the other of a metallic nature*—and that these images exist in varying proportions one to the other, and may be produced at will, depending almost entirely on the force and continuance of the light used in their production. With a weak light, and short exposures, the image will be principally organic; with a long continued and powerful light, metallic. This duality of the image seems to me to have been the stumbling-block over which we have so long continued to trip, and will explain the varying amount of permanence in proofs prepared in a *seemingly* identical manner. The organic image is, I believe, the image that fades, and this idea is supported by a variety of evidence. For instance, the lasting qualities of prints from delicate and thin negatives that are printed in a very subdued light to get the best impressions, are allowed, on all sides, to be less permanent than stronger impressions. For my own part, notwithstanding their attractiveness, I believe they are the most unstable of all photographs, and that such prints, without any doubt, no matter how carefully prepared, have but a short existence—ten years at the very outside, and frequently one or two. On the other hand, a strong metallic image—that is, one printed in a good light from a fairly dense negative—is, to all intents and purposes, quite permanent, if prepared with reasonable care. The theory of the duality of the silver print is not, if I may so term it, an upsetting theory, but merely an additional one. The ultimate forms that the varied and complex changes that take place lead up to is the production of a metallic and an organic image intimately combined, which although having different proportions, one to the other, cannot exist entirely separate.

The next stage in the production of a silver print is the toning. The substitution theory is the one generally accepted—that is, the silver chloride is abstracted from the image, and its place supplied with gold. The double chloride of gold and sodium or calcium becomes, by interchange of elements, the double chloride of silver and sodium or calcium, according to the salt used. If these reactions take place the abstracted silver should be found in the exhausted gold bath. May I ask if this has been satisfactorily determined by actual experiments? I have have heard this query put before, but have never heard the reply.

Supposing, however, a somewhat different action takes place, and, instead of the abstraction of silver from the image, each particle of metal becomes coated with gold—electroplated as it were—then an explanation is offered of the somewhat obscure changes that take place in this part of the process. An organic image would be obviously incapable of attracting a deposit of gold, otherwise of being toned, and the attempt to make it would result in the partial or entire destruction of the image. Adopting this theory, it is easily understood why a print from a weak, thin negative can never be made of a rich, deep colour, the small amount of metallic image with which it is combined being too little to attract sufficient gold before the bleaching effects of the toning bath upon the organic image has partially obliterated the impression. If the image be strong and rich, printed from a fairly dense bright negative, the toning can be carried much farther without this destructive effect taking place. By continuing its action the colour gradually loses its richness, but the image will not be destroyed in any reasonable length of time. The effect is, however, precisely the same. The destruction of the organic image takes place more or less according to the depth of the impression; but there is sufficient of the metallic image present to prevent the dual image being altogether effaced. The organic portion acts throughout as a coloured medium, to which most silver prints owe their warmth and richness, and the metallic part, to which they owe their permanency. We find by actual practice there is no *necessity* whatever to carry the toning process past a certain stage to ensure permanency. Even by stopping short of the most *perfect effect with regard to permanency*, we get an impression that will be sufficiently durable, so that there is considerable license in the matter of colour without incurring any particular danger. I think the very highest point to which toning can be carried with advantage is to stop it just before any reduction of the organic image takes place, known by the disappearance of half-tones; to carry it farther is at the sacrifice of richness and quality.

The desired colour being obtained, we come to the last chemical process the prints have to undergo—that is, fixing. To effect this we immerse the prints, well washed from the gold bath, in a solution of sodium hyposulphite, or thiosulphite, as it is perhaps more correctly called. Much stress is to be laid on the importance of using freshly-made solutions, and continuing the action sufficiently long to dissolve all that is soluble in the hyposulphite solutions from the paper. The time required varies with the temperature and the kind of paper; about a-quarter of an hour to twenty minutes usually suffices. No exact time can be stated, a very thickly albumenised paper requiring longer than samples thinly albumenised. The print should look clear when held up to the light, showing that the more opaque salts are removed. This part of the process, in my opinion, with a print lightly prepared in other respects, determines if it shall yellow and spoil, or remain bright and permanent. When the hyposulphite has effected its purpose and dissolved all those compounds which, we know by experience, lead to after-trouble, the proof must be thoroughly washed and dried. The results, I am convinced, are permanent impressions; and, so far as I can see, this is the result at which we wish to arrive.

In the foregoing remarks I have necessarily said much that is thoroughly well known; but my excuse must be, that without a rough sketch of the process of silver printing I could not point out those matters that, I believe, have so much to do with the vexed question of permanence. If others, by experiment, confirm the idea of a dual image, it will be obvious that the varying and puzzling results we have hitherto experienced can be reasonably explained, and will be a puzzle no longer. EDWARD DUNMORE.

ON THE ILLUMINATION OF THE DARK ROOM.

THE very unusual and, I believe, unprecedented course taken by the Editor of the *Journal* of the Photographic Society of Great Britain of printing Mr. C. Ray Woods' remarks, during the discussion on my paper upon the *Illumination of the Dark Room*, in form with a heading as though those remarks had been what is known as a communication to the Society, has doubtless been the cause of their being reproduced in your columns in the form adopted with papers authorised by the Council to be read at the Society's meetings. These remarks of Mr. Woods having thus gained such an immensely greater circulation than they would otherwise have obtained, I trust that you will allow me an equally public reply to them through the same channel.

One point that Mr. Woods addresses himself to is the defence of his use of the term "cathedral green." What I object to is the use of that term, as applied by Mr. Woods, to indicate any particular colour, seeing that blue-green and yellow-green, each in a variety of depths, may each be intended.

A matter that Mr. Woods particularly criticises is my statement that green glass (of the colour I showed) is a better protective supplement to stained red than the cobalt glass recommended by Captain Abney, and states as a fact—not as a mere supposition—that the reason I found it so was because I had not employed the precise red used by Captain Abney. Now, as I showed the results of two experiments with stained red glass, each of them being, like the pattern shown by Mr. Woods as Captain Abney's, flashed red on one side and stained silver yellow on the other, but not precisely of the same depth of colour, one being rather lighter and the other rather darker than Captain Abney's—and as with each of these pieces the green had given more illumination and more protection to the plate than the cobalt—there seems no probability that the use of a stained red intermediate between these two would cause a reversal of the result. If Mr. Woods, however, be still of opinion that with any shade of stained red glass cobalt is as good a supplement as green I invite him to send a piece of red and cobalt to any competent independent judges—say the Editors of this Journal, if they will undertake the experiment—and I will, on seeing the depth of blue to be competed with, supply a piece of green. I leave Mr. Woods free to select lamp light, magnesium light, or daylight, if he think that the choice will make any difference in his favour. He complains of my having used magnesium in this particular experiment; but, as this light comes between lamplight and daylight in actinic richness, it seems to me the fairest to select rather than either alone when trying mediums that are to be used with both.

It is noticeable that Mr. Woods leaves most of my arguments untouched. The proposition that red light has at least as much effect, or more, upon the sensitive film in proportion to its luminosity as yellow, and which was so strongly exemplified by Mr. Sawyer, cannot be said to be affected by Mr. Woods' experiments and remarks, as the relative luminosity of the red was not taken into account. The arguments—first, that the great difference of relative sensibility of the ordinary gelatino-bromide plates and collodion bath ones to different coloured light, which had so long been affirmed, did not exist, and, therefore, that the different *colour* of light required in the dark room in the two cases, which had on that account been insisted upon, was a mistake; second, that the great effect upon the colour sensitiveness of a bromide plate, caused by the addition of iodide, was also a mistake; and, third, that Captain Abney's experiments, which, it was thought, demonstrates the superiority of red light, were vitiated by the different conditions under which the comparison for photographic effect was made from those existing when testing the luminous power, the changes of conditions being favourable to the transparent medium, which happened to be the red—were all passed over, and it is satisfactory to see that South Kensington, as represented on this occasion by Mr. Ray Woods, found after a month's preparation nothing to say in reply to these propositions. W. E. DEBENHAM.

WHERE TO GO WITH THE CAMERA.

[It is hoped that this series of articles will be continued at regular and frequent intervals during the vacation months, and we shall be glad to receive contributions to the series from any friends able to treat of new and interesting ground.]

A WEEK'S RAMBLE IN NOTTINGHAMSHIRE.

I WAS tempted some little time after the introduction of gelatine plates to take a number of them, together with an 11 × 9 camera, to "Merrie Sherwood," and the series of pleasing pictures of sylvan and other scenery encourage me to recommend the land of Robin Hood to any tourist photographer in search of pretty woodland "bits" and picturesque ruins, &c., &c.

Taking an early train from King's-cross we reach the quaint old town of Newark, whose fine parish church and ruined castle of historic fame are well worthy of a visit. The former can be only successfully photographed with a lens of wide angle, the best view being obtained from Kirkgate; but even then it is wofully curtailed by the proximity of the adjacent buildings.

The castle may be "taken" from several points of view, enough of the ruins being left to make a very effective picture, and one not quite so hackneyed as that of the many much-photographed castles of the country. In a room of the castle, which is still intact, may be seen some interesting relics and a stuffed hound, the latter said to have belonged, when alive, to King John. A few hours will suffice for Newark, whence the train may be taken to Retford.

There is not much at Retford to interest one, unless it be the fine market-place on a Saturday, or the two churches of St. Michael and St. Swithin, both of which are very pretty. But from its excellent railway accommodation the town may be constituted one's head-quarters for a day or two, and first-rate accommodation is obtainable at the White Hart Hotel.

Fifteen miles from Retford, and a still shorter distance from the neighbouring town of Worksop, are the ruins of Roche Abbey; and a prettier bit of scenery than that in the immediate vicinity of the ruins cannot be found in England. The grounds of the Abbey are open to the public on Thursdays. Close by is the residence of a gentleman, an amateur photographer, who, on my visit, courteously gave me some information as to the neighbourhood and valuable assistance in taking my views. At least a dozen plates may be advantageously exposed on "bits" of "rock, water, wood, and dell," and artistic scraps picked out by the score. The ruins alone may be photographed from several points of view and make pleasing pictures, while the grounds, not spoiled by artificial cultivation, afford a profusion of photographic subjects.

Roche Abbey will "run away" with one day of the week, and a good day too. Another day may be spent in the woods. Taking train from Retford early in the morning to Chequer House, we walk thence to Normanton Inn, where we dine, and walk on either to Worksop or through the fine woods to Clumber, Thoresby, and through "Birklands" to the "Major Oak." Birklands is a remnant of ancient Sherwood Forest, and justly celebrated as being composed of some of the oldest oak trees in the country, gnarled and twisted into all manner of curious forms. The "major oak," being hollow, will accommodate sixteen persons.

Mine host of the Normanton Inn will give all the information necessary for finding one's way about in this woodland region. The inn is situate close to Clumber and the "Dukeries," and should the tourist be fond of sylvan scenery he cannot do better than remain here a few days and nights, when he will be treated to such bird music as will gladden a Cockney's heart. I hear from a correspondent that the nightingale is now in full song.

A few miles from Normanton Inn is Welbeck Abbey, the seat of the Duke of Portland—by no means a pretty building; but close to hand is the "Green Dale" oak, with a carriage drive cut through its stem—another "monarch of the forest." Near Normanton Inn there are also the pretty villages of Edwinstow and Budby, and within a few miles Rufford Abbey and the market town of Ollerton, not yet desecrated by a railway. Proceeding to Worksop we find the only object of interest to be the Old Priory gateway (which still remains intact), the Abbey Church, and Worksop Manor. These are each worthy of a plate. Going on by the Midland Railway to the village of Cresswell, the "Crags" (two rocky cliffs covered with trees and ivy, and with a lake between), are well worthy of attention, and five or six plates may be exposed.

Now, on again, per Midland Railway, to the old town of Mansfield. There is nothing very striking here but a few old houses and the parish church, &c. Then on to Southwell, where the minster will afford some recreation and an opportunity of using more plates. From Southwell we journey to Nottingham, unless, whilst at Mansfield, permission be obtained from Newstead to photograph that celebrated abbey, the home of Byron. This place being carefully looked after, permission is necessary before one can be allowed on the premises.

At Nottingham there is plenty to look at and plenty to photograph. Nottingham Castle, perched on a lofty cliff overlooking the vale of the Trent, first demands our attention, and makes a good picture. The market-place (the largest in the kingdom) on market day is a spectacle, and furnishes matter for a good instantaneous picture, whilst the Rock Cemetery, with its grottoes and chasms, is worth a plate or two as a memento of this curious and unique burying ground.

Close by the Trent is Clifton Grove, immortalised by Kirke White, and well meriting his praise, while with the village of Wilford by the "silvery Trent" we finish our pleasant ramble through the once romantic domain of "Bold Robin Hood"—

"A forester good,
As ever drew bow
In merry Sherwoo

About three miles from Nottingham is Wollaton Hall—a splendid building in (I think) the Elizabethan style. I have not photographed it, but, having passed by it a great many times, I am of opinion that it would make a nice picture if accessible to the tourist photographer.

I have here indicated the above short tour, embracing most of the principal objects of interest in my native shire; but should the tourist desire only pretty scraps of woodland scenery, he cannot do better or cheaper than locate himself at Normanton Inn for a week or so, where he can amuse himself to his heart's content. W. B. ALLISON.

THE ROYAL INSTITUTION.*

THE following is the conclusion of our translation of the lecture on *Colours* by Monsieur E. Mascart, Professor at the College of France, recently delivered in French at the Royal Institution, under the presidency of Mr. Warren De La Rue, F.R.S.

THE INFLUENCE OF THE SPECTRUM ON WATER FLEAS.

Is the vision of animals the same as that of man, or rather are there points of difference between them to the extent of their being able to see radiations which are invisible to us? To answer this question I will repeat a curious experiment performed by M. Paul Bert. In a glass vessel some water is placed containing a great number of small fresh-water shell-fish, belonging to the family of *Daphniadæ*. When a beam of light is sent through the vessel the water-fleas rush into it, and place themselves in the path of the rays. The greater part of the animals are in the same mood, and seek the light when it is not too intense. When we throw a spectrum upon the vessel, it is seen that the water-fleas again enter the illuminated region, but with differentiations which are very remarkable. The smallest of them swim about in the rays of the whole spectrum; a few of them in the red rays. They are abundant in the yellow and green, more plentiful in the blue and violet, and they are disseminated also in the ultra-violet. The largest water-fleas, on the contrary, take up a position almost exclusively situated between the green and blue. These animals see then the same rays as ourselves, despite the distance which separates man from crustaceæ in the zoological scale; and they appear even to partake of our infirmities, since some of them act as is they were affected by colour-blindness. Sir John Lubbock has made known in this same Royal Institution the results of a fine series of researches on the vision of ants, bees, and wasps, and brought out the very curious fact that the ultra-violet rays appear to ants brighter than the luminous radiations of the spectrum. The characteristics of animals studied in this aspect would be of the highest interest.

THE INFLUENCE OF COLOURS UPON LIFE.

So far we have considered colours but as the ornamentation of nature; but their influence upon the development of living things is exercised under the most varied conditions. Light and colours have, without doubt, a psychical influence, and this moral impression is nothing more than the translation of a physiological action.

In certain sanitary establishments for the treatment of the insane the patients have been made to live in golden-yellow light, which appears to exercise a happy influence on their character and to render them amenable to kindly sentiments. Certainly it is not the yellow sodium light which produces this result, but a sort of white light, in which the extreme blue and red rays are partly absent, so as to cause rose and yellow tones to predominate.

The predilection of animals for certain colours is not the result of artistic preference. If water-fleas seek the green light and ants the ultra-violet light it is without doubt because they find therein better conditions for existence.

Plants yield themselves well to this class of study. An ordinary plant—such as one of those which we have commonly under our eyes—grows, developes in every way, increases in weight, produces leaves, flowers, and fruits, and breathes; in other words, continual exchange is going on between the elements it contains and the gases of the atmosphere. These different acts of vegetative life are performed very unequally under the influence of diverse radiations—luminous or calorific.

The growth of a plant, by the elongation and multiplication of cells, takes place chiefly under the influence of the calorific rays, and for each plant there is the most suitable temperature. If a plant receive heat on one side only, it developes on that side and becomes stunted on the other.

In the light a plant grows more healthily than in darkness, but at the expense of its general nutrition and transversal development. Here the different colours have a very marked specific action. With a good light the retarding action, insensible with the invisible rays, presents a first maximum towards the red extremity, a minimum in the yellow where the light is the most intense, and a great maximum in the violet. The rays composed of short wave-lengths are, therefore, the most active.

This gives a simple explanation of heliotropy—that is to say, the tendency of plants to turn towards the light. When a plant is exposed to a lateral light, the lighted portions grow more slowly than those which remain in shadow; the plant consequently deflects its head in the direction of the light. On measuring this inflection, when set up by the different regions of the spectrum, it is discovered once more that the effect is insensible in the yellow, is more marked in the red, and has its maximum in the blue and violet.

We can deal now with the subject of the mechanism of nutrition. Besides the loss of water by evaporation, plants have two kind of respiration. One goes on continuously by day and night, and gives off carbonic acid gas; it is a sort of combustion correlative to life and is analogous to the respiration of animals. The other is intermittent, taking place only in the presence of light, and its function is to separate from the carbonic acid of the air the carbon of which the plant makes sugar and wood, at the same time disengaging the oxygen. The colouring matter of leaves, chlorophyll, plays the principal part in this nutritive respiration. The chlorophyll has to make itself in the first instance, then to exercise respiratory functions; and here, again, the different colours exercise a very unequal influence.

If the formation of chlorophyll in the plant is examined with an average light, it will be seen that it is produced throughout the whole length of the spectrum—very feebly in the infra-red, with a maximum in the intense yellow, and with a regular diminution extending into the ultra-violet of the solar spectrum. The curve of this action has a path analogous to that which Fraunhofer has given for the distribution of luminous intensity in the spectrum; but it is more prolonged towards the more refrangible end. Here, again, there is a preferential intensity beyond which the chlorophyll forms itself less easily. Beyond this a point of intensity is reached which destroys it, as in plants exposed to the full light of the sun.

Experiment proves that the production of oxygen does not take place except in the presence of grains of chlorophyll. If a ray of white light is made to traverse a solution of chlorophyll, and is afterwards analysed by a prism, an energetic absorption band will be seen in the red, and two others in the blue and violet. Now these are precisely the rays absorbed by the green substance which effects the decomposition of carbonic acid, and I cannot resist the desire to show you the ingenious method employed by M. Engelmann to put this fact in evidence.

In his experiments on fermentation, to which M. Tyndall has given such authoritative support, M. Pasteur has divided the little microscopic beings into "*aerobies*" and "*anaerobies*." The former breathe and grow in the presence of the oxygen of the air, but oxygen kills the latter. If we examine the first class of bacteria swimming in a liquid they will be seen to concentrate themselves around air-bubbles to get oxygen. If the liquid be deprived of air-bubbles and a piece of green weed is placed in it, the bacteria swim about indifferently so long as the light is very feeble; or, still better, if it have been passed through a solution of chlorophyll. But let white light be substituted, and the bacteria will be seen to precipitate themselves on all the grains of chlorophyll to seize the traces of oxygen disengaged; they constitute, therefore, a very delicate reaction.

To see the effects of different colours it is but necessary to bring a microscopic spectrum to bear upon a transversal cutting of a leaf. The bacteria will accumulate on the plant in the red just at the maximum point of absorption by chlorophyll, then in the blue, and the density of the population (so to speak) will almost follow the curve of absorption of the colouring matter.

I cannot dwell very long on the facts of natural history. I may state, however, that there are in this department great specific differences, bearing relation to the proper colour of different plants, resulting from the unequal absorption of their colouring matters. It will suffice to cite an example. The water of the sea has a different colour according to the thickness of it looked through by the observer, because of its unequal absorption of different radiations. Following the depth of the bottom on which it reposes, a marine plant meets with conditions more or less favourable, and is more or less well armed in the battle for existence. When we examine a sea-beach when the tide is out we find blue seaweeds near the level of high water, lower down green weeds, then brown weeds, and, lastly, red weeds in the regions which are rarely uncovered. At the upper part of a precipitous shore we perceive a series of bands of different colours which mark the limits where each species, better fitted as to physical conditions, has eliminated and vanquished neighbouring species; and this is not a question of depth, because we find the red algæ between wind and water in sheltered places, in the crevices of rocks, in deep caves, and where the light is of feeble intensity. In citing facts of this nature I am sure that you have all rising to your lips the name of one of the glories of England and of humanity—the naturalist Darwin.

Light, then, is the inexhaustible source from which living things borrow energy under all its forms and under conditions the most unexpected, and I request permission to close this lecture by citing some words of Lavoisier, which, when their date is taken into consideration, will appear perhaps to be a kind of divination:—"Organisation, sentiment, spontaneous movement, life, exist but at the surface of the earth, and in places exposed to light. It may be said that the fable of the torch of Prometheus is the expression of a philosophical truth which had not escaped the notice of the ancients. Without light nature would have been without life; she would have been dead and inanimate. A beneficent God, in giving light, has covered the surface of the earth with organisation, feeling, and thought."

IMPROVEMENTS IN AND RELATING TO COLOUR PRINTING, ALSO PARTLY APPLICABLE FOR PRODUCING COLOURED PHOTOGRAPHS AND FOR SIMILAR PURPOSES.

A communication by AUGUSTE BISSON, of Paris, France, heliographic engraver, to W. R. LAKE.

THIS invention relates to colour printing, but is also applicable for producing coloured photographs and for similar purposes.

The said invention comprises an improved method or process which is applicable to all kinds of photographic or other pictures, amongst which I will particularly mention the proofs obtained by means of carbon or salts of silver, such as those obtained by photoglyptic or phototypic processes. These pictures may be portraits, reproductions of natural objects, or pictures of any other suitable description.

The said method or process consists essentially in printing, impressing, or applying, in the special manner hereinafter described, the necessary colours, either directly upon one or the other face of the gelatine film bearing the carbon proof or the photoglyptic proof, or upon a proof obtained upon a translucid support—such as mica, vegetable parchment, dioptric paper, transparent mineral paper, and paper mounted upon cloth or the like—to which substances I impart complete transparency by means of an operation which I carry into effect either before or after the production of the picture. This operation consists simply in immersing the paper or other substance which is to be rendered completely transparent in a bath of varnish composed of the following ingredients, namely:—

Volatile or rectified benzine	1,000	grammes.
Resin	150	,,
Linseed oil	10	,,

This mixture is prepared in a water-bath, and by a simple agitation which ensures an intimate mixture of the materials.

The picture being perfectly transparent, either naturally or by means of the treatment above indicated, I effect the colouring in the following manner, that is to say:—When it is required to reproduce a picture I take a photographic proof produced by means of a salt of silver, upon which proof I apply as faithfully as possible, as a tone, either oil or water colours, in such a manner as to exactly reproduce the shades of the picture.

With regard to portraits, it will be sufficient to give a simple statement of the colours.

Having obtained this outline sketch or copy of the picture, or a pencil or crayon tracing upon any suitable paper, each outline having as a base the same tone or shade—that is to say, for example, a dozen different tracings are made, if there are twelve different shades in the picture, each tracing comprising only the outline surrounding one colour; each of these tracings is then placed upon a sheet of stout paper or cardboard, or a very thin and opaque sheet of material in order to intercept the rays of light for the subsequent operation—the outlines applied to the said paper, cardboard, or metal are cut out carefully. Then, this operation being completed, as many stones as there are pieces cut out are prepared; these stones are prepared in the dark or under the action of a yellow light, with a saturated solution of bichromate of potash in albumen or gum. When the said stones are dry, the opaque cut-out pieces are laid thereon at the places which are to be coloured; each stone is then exposed to the light, a piece of strong plate-glass being placed upon the said stone to cause the said cut-out pieces to properly adhere thereto. A complete impression or *facsimile* of the cut-out pieces is obtained after a few minutes' exposure, and the sensitive substance is afterwards removed by washing in the ordinary manner.

I then place successively upon each stone (taking care that each impression registers properly) either the carbon or the photoglyptic film, or the photographic or phototypic picture produced or transferred upon a support rendered completely transparent in the manner above indicated, in order to effect the impression of the colour either directly upon the front or upon the back of the film as required.

The stones being inked in the ordinary manner, the printing is commenced with the shades of the figure—in the case of a portrait, for example, the dresses and the like—and terminated with the flat tints of the flesh and of the costume.

The colours should be prepared so as to accelerate the drying thereof, which is completed in a drying stove similar to those used in printing establishments.

If it is only required to obtain a small number of similar proofs, it is advantageous to dispense with the printing operations, and to effect the colouring directly with the cut-out pieces which I term patterns, and which are obtained in the manner above described; this operation resembles oriental painting.

I paste upon the back of the picture, if necessary, a piece of transparent paper, such as vegetable parchment or mineral or dioptric paper, according to the colouring effect which I desire to obtain; then, after having made, by hand, the eyes, the lips, and other details of the portrait, I take successively the prepared count-out pieces, and by the aid of short brushes I successively apply, by means of flat tints, the different shades I desire to obtain, passing from one proof to the succeeding proof having the same colouration. When the oil or varnish colour is dry, I terminate the operation with the ground tone by causing a tinted paper in harmony with the subject to adhere to the back of the picture by means of varnish.

This process, which appears complicated, is on the contrary very practicable, as will be readily ascertained by making use of it. It will, moreover, be seen that, in either case, the long and costly employment of a designer and colourist is avoided by the application of flat tints obtained either by printing or by hand by means of cut-out patterns as above indicated.

The coloured proofs are finally mounted upon and caused to adhere by varnish, dextrine, or any other suitable substance to a support, care being taken to put the said proofs under pressure and allow them to remain so during a whole night. These proofs may be mounted upon panels or upon Bristol boards; the latter may be first subjected to a glazing or smoothing process, and then covered with an encaustic enamel or a light varnish to protect them from the action of the air.

As regards copies of pictures: they may be mounted upon cloth, and the illusion completed by intercalating a piece of any suitable fabric between them and subjecting them to a sufficiently-strong pressure during a whole night; the said copies will thus acquire the aspect of an oil painting on canvas, and may be mounted upon a wooden frame and varnished in the same manner as an oil painting.

Having thus fully described the said invention, I claim:—

The above-described improved method or process of colouration—by printing or impression—of pictures obtained by photography or by processes derived therefrom, which method or process is based essentially upon the following points, viz.:—

1st. The printing or impression of the colours upon one or the other face, either of the transparent gelatine film of proofs obtained with carbon or by photoglyptic engraving, or of these proofs transferred upon perfectly transparent supports, or of photographic or phototypic proofs obtained upon paper or other equally-transparent supports.

2. The above-described method of treating in a cold bath, formed of rectified benzine, resin and linseed oil, in, or about in, the proportions named, various partially-transparent supports, such as vegetable, dioptric or mineral paper, or vegetable parchment, in order to give to such supports a complete transparency.

3. The method of successive printings or impressions by flat tints of the different colours to be obtained by means of thin patterns made of opaque substance, such as metal, cardboard, or the like, which have been previously cut out to the exact outlines taken from a photograph of the picture of the different shades to be produced, and which are applied upon a lithographic stone treated with bichromate of potash to obtain parts representing the exact forms of the tinted parts, and which are then imprinted successively on the proofs suitably registered and prepared in the manner above indicated.

4. The modification of the method of printing, consisting in operating by hand, when only a few reproductions are required, by means of the cut-out patterns above indicated, which facilitate the rapid application, by flat tints put on by means of a brush, of the different colours which it is desired to obtain.

5. The above-described method of mounting the coloured proofs obtained as above indicated, upon Bristol board, wood panels, or cloth, according to the appearance which it is desired to give to the picture.

Meetings of Societies.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society, held on the 10th instant, the chair was occupied by Mr. A. L. Henderson.

Mr. W. M. ASHMAN, referring to some experiments described at the previous meeting by Mr. W. E. Debenham, said that he had experimented with hypo. baths since then. In one case he had added a considerable amount of strong liquor ammonia to a bath, and left a negative in it for thirty hours without its suffering in any way.

The CHAIRMAN inquired whether the plate had previously been subjected to the influence of an alum bath.

Mr. ASHMAN replied that it had not.

Mr. W. COLES had also experimented in the same direction. He had cut a plate in two, and placed one half in clean new hypo., and the other half in a collection of old used baths for three days. In neither case was the film affected, and he supposed that where it did dissolve that effect was due to some peculiarity in the gelatine.

The CHAIRMAN inquired whether anyone had experimented with formic acid as a developer for dry plates, as recommended by Mr. H. J. Newton, of New York.

Mr. ASHMAN had made some experiments which confirmed the view that formic acid was not a developer itself. He had poured some of the acid on to an exposed plate. The only result was that the gelatine frilled; there was no reduction of silver. He had also mixed bromide of silver, pyro., and formic acid in a test tube and exposed to light for some time; but again no reduction of silver took place.

Mr. A. COWAN exhibited a cutting wheel of American design in which the wheel was very much larger than in the old pattern. It could, therefore, be more easily sharpened and would cut several thicknesses of paper (certainly four) at one time. The rule against which it was to work should be both thick and broad.

The CHAIRMAN showed strips of the cardboard which had induced the broad, spreading marks of reduction on the plates with which they had been in contact, of which he had spoken at a previous meeting. He also produced negatives foggy all over which had been taken on plates packed with this cardboard, and he attributed the fogging to the spreading of the action of pressure or shearing stress set up at the edge of the card.

Mr. COWAN thought that the reduction or fogging was not due to pressure at all, but to chemical action.

The CHAIRMAN inquired whether Mr. Prestwich could give any information about marks resulting from packing.

Mr. W. H. Prestwich packed with a common thick paper or cardboard, and now never got markings. Formerly, when using cartridge paper, he did get them, but they did not spread.

The Chairman said that some few days since he had made several experiments with Mr. Cobb, and asked that gentleman to give the particulars.

Mr. W. Cobb said that Mr. Henderson had a few days ago written on some plates, and made marks with a pencil on paper laid over the films. These plates were cut in two, and parts developed at the time; the other parts were left until that day and then developed. Contrary to what had been anticipated, those plates which had been kept before developing shows the markings weaker than those which had been developed immediately after the marks were made. He (Mr. Cobb) further stated that he considered the question of dark markings on the edges of plates was an important one. He was in a position to state that pressure was not the cause, but that damp, either in the plates themselves or in the material used for packing, was. He had found these marks on some commercial plates which had been kept upright in grooved boxes and not subjected to any pressure. Some of these plates he produced. Some months since he had all the paper that was to be employed for packing thoroughly dried before being used, and with plates thus packed he had not found any markings at all. Since then he had in one case omitted to dry the paper first, and the batch packed with this paper had, as he remembered, taken a long time to set. When they were opened a short time since an image of the paper was found to develope on the plates, but where the paper had slipped in packing and the plate was uncovered it developed clear.

Mr. F. York inquired what kind of paper had been used.

Mr. Cobb replied that it was chrome yellow paper similar to that used for dark-room windows.

Mr. York had seen markings such as those referred to on plates packed both in cardboard-grooved and wooden-grooved boxes, and whether kept upright or stored flat.

The Chairman considered that it was a serious matter, as there seemed to be three dangers to guard against. If the paper were damp that was said to produce marks; if well dried there was danger of phosphorescence; and then there was a danger of chemical effect from the paper itself.

Mr. Cobb thought that the proper course was to dry both plates and paper well before packing. He also showed some parchmentised paper, which was what he now used for the purpose.

Mr. Ashman remarked that parchmentised paper, which was simply paper passed through sulphuric acid and washed, had the advantage that it did not readily absorb moisture.

Mr. York inquired whether all the acid was washed out after parchmentisation. Perhaps Mr. Haddon would explain the action of the acid.

Mr. A. Haddon said that there was simply a dehydration—the removal of the elements of water from the substance of the paper.

A Member inquired whether any experiments had been recorded of the effect of pressure in producing phosphorescence.

The Chairman said that such would be found in one of the photographic journals.

Mr. P. G. Graham remarked that some fifteen years ago he had packed up plates which a gentleman well versed in emulsion work had said would not keep, owing to the process by which they were made. His own opinion was that they would keep, and packets that had been opened from time to time bore out this view; in fact, they were now even better than at first. The method of packing employed was to take a long strip of yellow and orange paper—similar to that mentioned by Mr. Cobb—as wide as the length of the plate, and to wind this round every two plates, placed back to back, till the dozen was made up. In every case the paper was carefully dried before use. Small and large-sized plates were stacked in one box, one packet upon another, in grosses, so that the pressure on the bottom packet must have been considerable; but in no case had he found any marks from pressure.

The Chairman passed round a silver print on opal, printed right out, and sent with a letter, which was read, by Mr. J. Crosby, of Rotherham.

A Member inquired the details of manufacture, and it was suggested that the Secretary should write to Mr. Crosby for particulars.

The Chairman exhibited some plates showing effects which he thought explained the reason why from the same batch of emulsion some plates were quicker than others. He attributed it to the greater or less time they had taken in setting. On a summer afternoon, when the temperature was high, the emulsion would take so long to set that the coarser bromide had time to settle to the bottom. With some that had taken from twenty to thirty minutes to set, he found that they acted with quite half again as much sensitiveness when exposed from the back as when exposed on the front. The more quickly plates were set the more rapid and uniform they were. He also thought that this settlement of bromide would explain one cause of frilling, the bromide preventing the gelatine from adhering. He (the Chairman) also mentioned that someone from abroad had called on him to prove the superiority of a new secret developer. On making careful experiments, however, against his (the Chairman's) own developer the secret one was found to give less detail and more green fog.

The Chairman being about to start for America the best wishes of the Association were accorded to him, and it was suggested and acquiesced in that during his absence he would send to the Association leaves from his note-book.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

This Association held its usual Board meeting on Wednesday, the 2nd instant, at 181, Aldersgate-street, E.C.

The minutes of the previous meeting were read and confirmed. Mr. T. W. Cowper was elected a member of the Association.

The correspondence and other matters having received attention, the meeting terminated.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The fifth outdoor meeting for the present season of the above Society was held on Saturday, the 12th inst., at Matlock Bath.

As announced in the list of summer meetings issued to the members at the beginning of the season, the time of departure from Manchester was fixed for one o'clock p.m.; but at the subsequent request of several gentlemen who wished to devote a greater portion of the day to photographic work in so beautiful a locality, it was decided to travel by an earlier train. This change having been made known amongst the members as widely as possible, the party left the Central Station at 9.50 a.m., arriving in Matlock a little before 12 o'clock at noon. Notwithstanding the extremely unsettled state of the weather, and the prevalence of thunder-storms during several days previously, the morning opened delightfully fine; and, with the exception of a stiffish south-westerly breeze, the weather throughout the whole of the day could hardly have been more propitious.

In accordance with a prior correspondence with the secretary of the recently-established photographic society at Derby, a trip to Matlock had also been arranged by that Society for the purpose of meeting, and fraternising with, the Manchester party; and it is much to be regretted that, partly owing to the unavoidable absence of Mr. Warburton—who should have "generalled" the Manchester members on the occasion—as well as to an imperfect knowledge of the surrounding district, the party, acting under local guidance, had somewhat unwittingly committed itself early in the day to a long drive, which unfortunately prevented the meeting with the Derby members until late in the afternoon.

Successful negatives were obtained of the High Tor, Heights of Abraham, Lovers' Walk, and some general views of the town, the configuration of the ground on which Matlock stands being singularly favourable for giving the necessary "coigne of vantage" at several different points.

Access was procured to the grounds adjacent to Willersley Castle, where some views were obtained on the Derwent; also of the beautiful and picturesque little church, founded by Sir Richard Arkwright, at Cromford.

Lea Hurst, the residence of the noble-minded and self-sacrificing Florence Nightingale, was also visited, and permission having been obtained several plates were exposed, in some of which the party was grouped on the lawn. The house is delightfully situated. The simplicity and taste with which the grounds have been laid out give the place an air of peace and retirement, befitting, as one would think, the residence of a lady whose life hitherto has been a mission of mercy.

The return drive was by Crich Hill, where, as the result of a peculiar geological formation in the heart of the mountain, a serious landslip occurred some two or three years ago. The views from the tower on the summit of the hill (but not photographic views) can hardly be surpassed for extent and beauty. At this point, however, time was becoming a serious antagonist, and the remainder of the journey to Matlock was made with all possible dispatch. A hurried tea was taken in company with the Derby brethren, and, at the suggestion of Mr. McKellan, supported by several others, it was proposed that a special day trip should be shortly arranged for a joint meeting of the two societies at Ashbourne, for the purpose of working the charming and romantic scenery in Dovedale. It is to be hoped, if such a meeting should be arranged (and of which due notice will be given), that the Manchester Photographic Society will muster in strong force—not only on account of the grand and imposing scenery to be met with in Dovedale, but also to give the right hand of fellowship to the representatives of the Derby Photographic Society.

The next outdoor meeting of the Society is proposed to take place at Speke Hall, on Saturday, July 26th. The train will leave London-road station at 10.20 a.m. Members and friends will please to send in their names to the leader, Dr. C. P. Bahin, Stanley House, Heaton Moor, two or three days before the date of the excursion.

LEEDS PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held at the Philosophical Hall, on Thursday, the 3rd instant,—Mr. J. W. Ramsden in the chair.

After the confirmation of the minutes, Mr. Whitham was elected a member of the Society.

Mr. Washington Teasdale called attention to a number of very fine lantern slides which he had taken on Ramsden's special lantern plates. He said the plates were very slow, the exposure required being from thirty seconds to two minutes (according to the density of the negative), at a distance of twelve inches from a fish-tail burner. The tone of colour obtained by the pyro. developer was a rich brown, and the great characteristics of the plates was absolute clear glass in the shadows, with the best gradation of tones and half-tones that he had ever seen. He also drew attention to two or three slides that had been transferred from the fixing-bath to the alum solution, the result being a red stain.

Mr. Pocklington had also been using the same plates and got very fine results, some of the most effective being those toned by immersion in a bath of—

1.	Nitrate uranium	20 grains.
	Water	1 ounce.
2.	Ferridcyanide of potassium	20 grains.
	Water	1 ounce.

Two parts of No. 2 to one part of No. 1.

In answer to a question as to what was the cause and the best cure for flare in double combination lenses, it was suggested that flare was very frequently caused by the front lens being in a dirty condition.

Mr. H. Rodwell remarked that the lens of the scenograph always gave a flare-spot when used with the smallest stop, and as a preventive an additional stop was supplied to fix in front of the other.

In answer to a question as to what was the best way to recover the silver from a quantity of soda and water in which the films of several gross of negatives had been dissolved, and as to whether it was worth doing, Mr. J. W. Ramsden suggested a number of methods that might be employed, but thought the best would be to add a quantity of sawdust to the liquid and then reduce in the usual way. In his opinion, however, the result would not be worth the trouble, seeing the very small quantity of silver used to make the image.

A Member asked the following question:—He had an etching copyright of a very valuable painting. Supposing he made for his own use, and for exhibition in his own home to his friends, a lantern slide, would he be liable to any prosecution if it were known to the owner of the copyright that he had done so?

A long and interesting discussion took place. At the close it was generally agreed that in doing so the member would be liable to prosecution, and if convicted the owner of the copyright could obtain damages; but, if the slide were used only in the way described, the damages would be so small that it would not be worth the while of anyone to incur a long and costly trial to obtain them.

An inquiry was made as to whether any of the members had seen the "vulcanised fibre" that had been recommended for making shutters for dark slides, &c. Although several of the members had heard of it none had seen it, and it was not known where it could be obtained. From a description given in one of the journals it was thought that it would be very useful, not only for shutters, but for stops, &c.

Mr. Teasdale said he deprecated the use of brass for stops, and had used for some time stops made of ebonite, as being much better; but he thought that if the Willesden paper were supplied in black it would be most useful, not only for this purpose, but for many others where thinness, toughness, and lightness were required.

Mr. Ramsden exhibited a very portable camera and instantaneous shutter adapted to work close to the back lens. They were much admired.

The meeting was then adjourned

GLASGOW AND WEST OF SCOTLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

A special meeting of this Association was held in the new rooms of the Association, 180, West Regent-street, on the evening of Thursday the 10th instant,—Mr. Hugh Reid, President, in the chair.

After the adoption of the minutes the following new members were admitted:—Messrs. John L. Coulson, David Pratt, James Kirkwood, Samuel Walker, William B. Smith, and James Torrance.

It was agreed that any amateurs visiting or passing through, but non-resident in, Glasgow should have the use of the dark room, &c., without charge, on the introduction of any member of the Society.

After a little discussion it was arranged that the next outdoor meeting of the Society should be held at Kilmun and Holy Loch, on Saturday, 9th August. Members to leave by the 8.30 a.m. train from St. Enoch's Station.

The members present were very much pleased with the new rooms, and it is expected that the Association will derive great benefit from the increased accommodation for meetings and the conveniences of the dark room for developing, enlarging, &c.

After the usual votes of thanks the meeting was adjourned.

OLDHAM PHOTOGRAPHIC SOCIETY.

On Tuesday, the 24th ult., the members of this Society with a few friends visited Bakewell, Haddon Hall, Chatsworth, and Rowsley, in Derbyshire. The day was favourable. Fourteen cameras were at work, and about 100 plates, varying from 12 × 10 to stereoscopic size, were exposed. On development the quality of the majority of these plates have turned out satisfactory. After passing an enjoyable day the party, numbering thirty-one, partook of an excellent tea at Rowsley, and returned by a quick train at eight o'clock p.m.

The monthly meetings of this Society are now held at the Oldham Lyceum, the first meeting at which place was on Thursday, the 26th ult., when thirty members attended,—Mr. John Risley, President, in the chair.

A good show of work by members was exhibited, and the Chairman brought a new drop-shutter of his own invention before the meeting, the simplicity and perfection of which secured great praise.

Six new members were proposed at the meeting. This Society was established in 1867. It now consists of over fifty members, and is in a most healthy condition.

DERBY PHOTOGRAPHIC SOCIETY.

An outdoor meeting of this Society was held at Matlock, on Saturday last, the 12th inst. Among those present were Messrs. C. E. Abney, C. Bourdin, S. J. Cholerton, T. Scotton, F. Shute, F. W. Simpson, and R. L. Warham.

Starting from Derby at 2.5 p.m., the party alighted at Matlock Bath station, and immediately set out for the well-known High Tor. The weather at starting was everything that could be desired; but no sooner was the formidable array of cameras pointed at the gigantic rock than a black cloud obscured the sun. "Everything has an end," and this proved true with regard to the cloud; for, after waiting patiently for some time, the weather cleared up and the sun again shone. Having secured this picture a move was made to the "Lovers' Walk," and here the party met two members of the Manchester Photographic Society.

Some views of the river and "Lovers' Walk" having been taken, the members next drove to Cromford, where they met the rest of the members of the Manchester Photographic Society, and returned with them to Matlock, where the two societies "tea'd" together at the Peveril Dining Rooms.

The President of the Manchester Society (Mr. J. Pollitt), in the course of a few remarks, invited the Derby Society to join them in an excursion to Dovedale during the summer. The members then separated.

Correspondence.

TRANSPARENT MARKINGS ON GELATINE NEGATIVES.

To the Editors.

Gentlemen,—In your issue of the 4th inst., my friend Mr. A. Pringle complains of many of his plates being spoilt by being marked about an inch or so from the margin with an insensitive band; and another correspondent in last week's issue makes the same complaint.

I also have had considerable trouble and loss from the same cause; but I cannot agree with your correspondent, Mr. D. W. Hill, as to the reason of this—at least in my own case, as I have used the plates in slides having no hinge. I have noticed, however, that the tissue paper which is placed between the plates in packing is not always the same size as the plates, but generally half-an-inch narrower all round. The insensitive line is not always on the same side of the plate with me; but sometimes on the right, at other times on the left, occasionally along the top or bottom, and again sometimes round two sides. May not undue pressure where the paper ends be the cause of this marking? If so, the remedy is evident.

I may say that I have some plates of the same make which have the paper entirely covering the plates to the edges, and no such markings have I ever found on these; in fact, they are the finest and most perfect plates I have ever used.—I am, yours, &c., John Jackson.

Friar's Mount, Waverley-road, Clifton, July 12, 1884.

BLISTERS IN PRINTS.

To the Editors.

Gentlemen,—It would, I think, be a great boon to all photographers if some of our able experimentalists would kindly investigate the cause of blisters in silver prints. So far as I am aware this has not yet been done systematically, as was the case with the question of the action of hypo. in fixing, and of which you have given us such a well-timed and useful reminder in this week's Journal.

What we want to know, *with certainty*, is the cause of these annoying defects. At present I think all that is known amounts merely to one or two empirical notions.—I am, yours, &c., "Bromo."

Leamington, July 12*th*, 1884.

THE PHOTOGRAPHIC SOCIETY AND ITS REPORTS

To the Editors.

Gentlemen,—The length to which Mr. Herbert B. Berkeley's letter in your last issue extends makes the task of digesting and replying to it seem rather appalling; but, as my name is referred to more than once, I will endeavour shortly to answer some of Mr. Berkeley's remarks.

Mr. Berkeley comments upon my objection to the "slip system" by saying that he has a higher opinion of men than I have, and that it would be more complimentary to my fellow-members if I were to give them credit for not seizing opportunities for "cooking" the reports. Is Mr. Berkeley's opinion of men so high that he is prepared to guarantee of every person who may happen to become a member of the Society that he would not do so? In the particular case to which I referred I imputed nothing unworthy to the member the alteration of position of whose remarks made mine appear absurd. He might well have thought it was desirable to put his two remarks into one sentence, and, not having the slip of my observation made between them before him, would not see that he was doing injustice to me or anyone; or it may have happened that the slip was furnished to him with his two sentences condensed into one.

As to the argument that any error in the Society's *Journal* can be corrected in the same publication, but that such a protest would seldom be required: I would point out that the time which must elapse before such correction could appear is longer than most people like to lie under a misrepresentation which may make them appear ridiculous. A month is the shortest time, and at present it will be nearly half a year. At the last ordinary meeting, for instance, Mr. Sawyer said that he should like to have the opportunity of exposing a plate for five minutes to the light of my composite light lamp. This was reported in the Society's *Journal* for June; but my reply that he should be most welcome to do so, and that I should be pleased to furnish him with any of my patterns, was omitted from the report. Now the Society's *Journal* will not in the ordinary course appear again until nearly Christmas time.

Mr. Berkeley says that the reporters do not take down the speaker's actual words. I do not know what is his authority for this statement, but I believe that in important cases they commonly do take down the actual words, although when writing out the report for publication they necessarily condense, and omit repetitions, &c.

Mr. Berkeley is very broadcast in his charges of misrepresentation. "The Editors, like the other writers, totally misrepresent my meaning," he says. Misrepresentation is a more serious charge than Mr. Berkeley seems to think; and, as he has not given any instance of what he calls misrepresentation on my part, perhaps he will think proper to withdraw his charge—at all events so far as I am concerned.

In a letter in the same issue of the Society's *Journal* as that from which you quoted Mr. Berkeley's first letter is another by him, in which he complains of my having attributed to Mr. J. B. B. Wellington the first production of beautiful warm tones upon bromide plates similar to those obtained upon chloride, and claims priority for himself. In support of this he refers to a print which had been for some years in the possession of Capt. Abney, the editor of the Society's *Journal*, and in a footnote Capt. Abney confirms his claim. Mr. Berkeley refers to having published the matter some seven years earlier. I have looked through some volumes of photographic publications without finding the reference, although I have come across a good deal of writing of Mr. Berkeley's in support mainly of two propositions—one that it is better to use excess of silver in making bromide emulsions; and the other that chloride of silver would, when a proper developer was discovered, be found more sensitive in the camera than bromide. (This was before Dr. Eder's publication of the method of using iron developer, which has so popularised the chloride process.) I have not yet met with the description of the method of producing warm tones on bromides. Will Mr. Berkeley kindly furnish the date? It is unaccountable, if his results were in beauty anything like those of Mr. Wellington, that the matter was not taken up and made much of at the time and largely employed since.

In answer to Mr. Andrew Pringle, I heartily accept his apology for charging me with want of courtesy. Had I accused him of "want of logic" generally, I should feel an apology due in turn from me. As, however, he has withdrawn the complaint, which appeared to me to be illogical, there is nothing more that need be said.—I am, yours, &c.,

July 14, 1884. W. E. Debenham.

THE PHOTOGRAPHIC SOCIETY.

To the Editors.

Gentlemen,—Will you allow me a few lines in reply to Mr. H. B. Berkeley's letter in your last.

As one of the "anonymous ones," may I point out that my letter and those of others were not "personal attacks" on Mr. Berkeley, but were reflections upon the conduct of the Society whose self-elected spokesman and champion he had become. If Mr. Berkeley chooses to write in his own name, with the chance of having the council and officers to back him, it is no reason why a humble private member should follow his example with the certainty of having the same august body—to use Mr. Berkeley's elegant expression—"down on him like a load of bricks."

Mr. Berkeley's last letter has not added one single new argument to his previous ones, nor has it shaken a single one of the counter arguments. It may, in fact, be taken as a type of what we may expect when the "slip" system becomes general; it is an extension of what *was* said for the purpose of explaining what was *intended* to be said.—I am, yours, &c.,

July 14, 1884. A Member.

To the Editors.

Gentlemen,—In Mr. Herbert B. Berkeley's somewhat wordy communication last week the writer speaks of the valuable matter which I and my friends barter over the attractions of the refreshment table. Allow me to point out, as Mr. Berkeley is so particular on the point of "misrepresentation," that I spoke in my previous letter of the valuable information which "passed from one to another," &c., &c. Now, I find the dictionary gives the meaning of "barter" as "to give one thing for another"—"to traffic by exchanging."

If Mr. Berkeley's photographic ideas do not soar any higher than bartering or exchanging, I would inform him that there *are* a large number of the members of our Society who are willing to impart information and advice without expecting any *quid pro quo*.—I am, yours, &c.,

July 15, 1884. Looker On and Listener.

REPLIES: ILLUMINATION OF THE DEVELOPING-ROOM AND OTHER MATTERS.

To the Editors.

Gentlemen,—I have of late been so much before your readers, controversially and otherwise, that I feel myself not only justified but constrained to retire into my shell, and to cease to occupy more than necessary of your valuable space. This being the case, allow me to notice as succinctly as possible the various writers who bring my name into their communications in your issue of today.

My first antagonist is my very good friend the Rev. H. V. Macdona. That gentleman asserts that I have "taken an idea into my head, and am riding it to death." What "idea" does he mean? The "idea" that ruby is preferable to yellow for a dark room window is pretty old, and was taken into the head of men superior, as they were anterior, to me in photographic science. And if Mr. Macdona will read my articles he will find I am far from riding anything to death; for my distinct advice is that every man should use what colour he likes and finds best, the gist of my writing being a warning, founded on medical authority, to make sure that the eyes are not damaged by the change so much urged on us. That is the Scotchman's way of "riding to the death"—boldly, but carefully. Mr. Macdona's "illustration" has certainly nothing Scotch about it; in fact, it smacks of the "sister island." After having "given great attention to the different testimonies" * * * * he feels "perfectly convinced that a great boon has been conferred * * * * by the happy discovery of a medium which combines the maximum of luminosity with the minimum of actinity." The "happiness" of the discovery is the very point upon which we are at issue; in fact, Mr. Macdona "begs the question" in a thoroughly jovial and good-natured manner.

Mr. D. W. Hill's notes on *Transparent Markings* on negatives are evidently written with the intention of helping me out of a difficulty, and I thank him cordially. But that my markings did not arise from the same cause as his will be apparent from the following facts:—Other plates used in the same camera did not give the same effects, while the faulty plates used in other cameras did. My marks were not always at the same end of the plate; they were often not at the end at all, but at the sides. My plates did not lie in slides at all, but in a changing-box; and my slide for the changing-box has not india-rubber American cloth in it. As a matter of fact, the fault lay in the drying of the coated plates; and the manufacturer behaved all along in the most handsome way, trying to discover the cause of the mischief. Now that he has rearranged the drying-room of his establishment, he is sending me plates as perfect in their coat as they are in other respects.

I seem, from Mr. H. B. Berkeley's remarks of July 5th, to have misrepresented or misread his letter to the Parent Society's *Journal*; but I seem also to have sinned in a numerous, if not good, company. The very fact of so many people having misrepresented or misread his letter speaks pretty strongly for the truth of what I before alluded to—the difficulty of seeing what he really did mean. It appeared to me when I wrote, as it appears to me still, that the *Journal* of the Photographic Society of Great Britain cost more than it was worth, and I see no reason why I am not to say so. Mr. Berkeley's letter brought the conduct of the *Journal* into public notice, and I had my humble finger in the pie. I am myself a member of the Society in question, and, in spite of Mr. Berkeley's insinuation pretty broadly stated, I am not one of those who pay their guinea with one hand and *decry* the Society with the other. I have every wish for the prosperity of the Society, and by what right I am accused of wishing otherwise I am at a loss to discover. If the members of the Society are to show their interest in its welfare by silence, whatever may happen, we had better put up the shutters, or "sport our oak" and docket it—"Back in five minutes." On such conditions I have not another word to say. My chief comfort is that in his letter of July 5th I do not suppose Mr. Berkeley represents the Society as a body, nor will I believe that the Society as a body considers itself beyond the reach of honest and frank, but thoroughly well-meant, criticism.—I am, yours, &c., Andrew Pringle.

Craigcleugh, Langholm, July 11, 1884.

Notes and Queries.

R. Beard sends us two safety valves constructed on the principles described by Mr. Hardwich. We hope soon to be in a position to try these, after which we will report upon them.

"Opaque" desires the names and addresses of certain makers of lanterns to which allusion has been made in this Journal.——It will be necessary for him to specify particulars before this request can be complied with.

G. Dobbs asks—"Does the Government guarantee me anything when I register a photograph by entering it at Stationers' Hall?"——We reply: By this act Mr. Dobbs is enabled to bring an action against anyone who, by copying his picture thus entered, infringes his copyright.

"By what means can I cement a trough that will hold acid solutions?—B. S. Boyle."——In reply: Let our correspondent mix together equal quantities by weight of pitch, resin, and plaster of Paris. First melt the pitch; then add first the resin, and lastly the plaster, which must be quite dry. This forms a cement suitable for the purpose mentioned.

A. M. Donaldson says:—"I have a quantity of home-made spirit of wine which is pretty strong, and which I intend employing for photographic purposes. But I have not taken any special precaution to get rid of the last traces of fusel oil which, from my manner of proceeding, I suspect must be present in some small degree. Can you inform me of any means by which I can detect the presence of this oil?"——In reply: There is a very excellent way of ascertaining the presence of fusel oil in alcohol, but it depends on the sense of smell. Break up some chloride of calcium into small pieces and put them in a beaker; then add just sufficient of the spirit to moisten the whole. Cover the beaker and allow it to stand. In a short time the smell of fusel oil, if any be present, will be distinctly perceptible, and increase in intensity after standing for some hours. The slightest trace of fusel oil may be detected in this way.

T. J. Hart asks—"What is a 'chemical focus?' I have a hazy sort of idea concerning the meaning attached to the term by many writers, and I think them wrong, if my idea be correct. Perhaps you will kindly say what is meant by the term, and also if it be a correct one to apply to an optical instrument."——We reply: The term is commonly employed to distinguish between the visual focus of an imperfectly corrected lens and the focus at which most of the chemical or active rays are brought to a point. It is this latter that is spoken of as the "chemical focus," in contradistinction to the "visual focus," which is situated on a different plane. In popular phraseology, when a lens is said to have a chemical focus it simply means that it is not properly corrected for colour. The best lenses have their visual and chemical foci coincident. On the subject of the correctness of the expression employed we shall not here make any comment. The language of strict optical science does not always apply to photography, which has a nomenclature peculiar in many respects to itself.

J. Jobson has experienced some difficulty in obtaining transparent oil colours for painting lantern transparencies. Those he has secured are somewhat opaque and lacking in brilliancy. This is especially the case with the greens and reds. He inquires, too, if there be no better yellow than gamboge.——In reply: Our correspondent is not the only one who has experienced the difficulty just described. We are pleased at being in a position to indicate a termination to his troubles. Mr. Newman, of Soho square, has succeeded in producing some transparent oil colours that are simply admirable. A green, which is very brilliant and perfectly transparent, is issued by this firm in small tubes, under the designation of "chromium green oxide," which is a most useful colour, answering well for foliage. The "carmine madder" of this firm is the most brilliant red that is necessary, and is quite transparent; equally transparent is a new yellow, which is issued under the name of "aureolin." We are glad that a firm of such high reputation as that of Newman is bestowing attention upon the more difficult class of transparent colours for lantern pictures.

Exchange Column.

I will exchange a 19 × 16, and 8½ × 8½, camera for anything useful; see advertisement.—Address, W. Hudson, 62, High-street, Bordesley, Birmingham.

I will exchange a burnisher, nine-inch roll, new, for a three-wick lantern or slide.—Address, G. V. Sankey, photographer, Woodville, near Burton-on-Trent.

Wanted, a 5 × 5 square bellows camera, folding tailboard, with one single and one double slide for coil, in exchange for sewing machine or lantern slides.—Address, C. J. Emery, Walton, near Ipswich.

I will exchange a whole-plate landscape lens, rack and pinion, perfect definition, for a quarter-plate (or larger) portrait lens; photograph submitted and required.—Address, M., care of Mr. Joseph Wild, Charlotte-terrace, Farnworth, Widnes.

I will exchange a Grubb's patent portrait lens, two and a-quarter inches, front lens fitted in separate mount, also a solid ivory walking-stick, splendid fishing-tackle, case, and waterproof fishing bag. Wanted, a rectilinear lens or whole-plate folding camera.—Address, W., 8, High-street, Kington, Herefordshire.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

T. Bourke.—We regret we cannot supply you with the gentleman's present address. He has removed quite recently.

W. Bennett.—You had better apply to the makers of the paper. They may possibly be able to supply you with a formula for a warmer tone.

Geo. B (Hants.).—See article in the present number. We shall be very much pleased to be informed of the result of your experiments in that direction.

R. C.—We believe the apparatus to which our correspondent refers is that styled the "*multum in parvo* tripod stand," manufactured by Messrs. H. Newton and Co., Liverpool.

Hypo.—If the solutions are concentrated such a result will certainly occur; but with weak solutions there will probably be nothing further than a slight deposit formed after some time.

A Yorkshire Amateur.—During the hot weather try treating the plates with a solution of alum before fixing them. This will, no doubt, prevent the minute blisters of which you complain.

Instantaneous.—The thing is much better in theory than in practice, unfortunately. No one has yet succeeded in producing anything like good results; but do not let this deter you from experimenting, however, as you may be more successful.

Printer.—If by "muddiness" our correspondent means what is usually known by "mealiness," it is probably caused by not allowing sufficient time to elapse after adding the gold. Twenty-four hours should be allowed. "Printer" had better forward us a sample print.

H. K.—1. The transparent spots appear, judging from the prints, to be due to air-bubbles adhering to the film during the development. The only remedy now is to touch out the spots with india-ink.—2. See answer to "A Reader (Brighton)."

B. G. Y.—You cannot possibly do any harm by removing the lenses from their cells and blackening their edges, as you suggest. On the contrary, they will be improved by the treatment. We are surprised that the maker should have sent out the instrument without first taking this precaution against reflections.

Giaggiolo.—Are you sure the defects proceed from the emulsions at all? It is possible, after all, that it is not due to the fixing solution being too strong. Try fixing in a bath composed of one part of a saturated solution of hyposulphite of soda diluted with three parts of water. If this do not get you out of the trouble write again, sending us an example.

J. Ewings.—The groups of fish are very artistically arranged. The only fault in connection with the pictures is that the negatives are somewhat under-exposed. If you had given a longer exposure the silvery scales of the salmon would not be so chalky, and the shadows between the fish less heavy. The group of mackerel is the best of the series. That is fully exposed.

An M.D.—The photographs, as pictures, are not what might be called "first class;" but, for the purposes of your profession, they, we may say, should prove very valuable if published. For such purposes the technical excellences of the photography is only of secondary importance. These prints appear to show every detail, and that is all that is requisite. Such subjects can never be made into artistic pictures.

W.—The stain is caused by the negative being insufficiently fixed before you proceeded to intensify it with the mercury. We know of no practical method by which the stain can now be removed. In future you will do well to allow the negative to remain in the fixing solution for a much longer time than is apparently necessary to dissolve out the bromide—more particularly when the negative has to be intensified afterwards.

L. J. H.—About the only thing you can now do to improve the picture is to introduce a few clouds. These would make a vast improvement. Had you employed a smaller stop in the lens the definition would have been much finer. So far as we can judge from the print the negative appears to be fully exposed. If you print-in the clouds, as we suggest, you will be surprised at the difference it will make in the appearance of the photograph.

G. F. T.—1. The experiment is worth making, though we can scarcely tell you what is "likely to be the result" without ourselves performing it. As it will be quite as easy for you to do so, and as you are probably more interested in the matter than we are, we should decidedly recommend you to test the question for yourself.—2. Infusion of quassia was recommended as a preservative for dry plates as far back as 1868. We see no reason why it should not be utilised in connection with gelatine if it have any advantages.

J. Cohen.—To get a more metallic appearance in the deposit on glass positives you must add a little nitric acid to the developing solution; indeed, if a very metallic image be required, the acetic acid may be omitted entirely, and replaced with nitric. The following will give a very bright deposit:—Sulphate of iron, fifteen grains; nitric acid, five drops; water, one ounce.

S. R.—1. Now that you have added the two residues together your best plan will be to precipitate the silver with sulphide of potassium (liver of sulphur). In future they should be kept separate. The old developing solution from gelatine plates is of no value, and certainly should not be added to the washings of prints, as the ammonia would tend to dissolve the chloride of silver when formed.—2. To prevent reflection from the edge of the aperture.

Jas. Watkins.—From your description the failure appears to be due to the tissue not containing sufficient colouring matter to prevent the light penetrating through the film to the paper; hence the reason you cannot remove the latter to develope the print. Try again, and add a little more india-ink. The tissue you have made may be utilised for printing from weak negatives. It is only very strong ones that will print through and cause you trouble.

A Reader (Brighton).—The reason the bath refuses to tone is that, for some reason or other, the gold has become precipitated. This is proved by the black deposit on the sides and bottom of the bottle. It is impossible for us without being made acquainted with all the details to assign the cause. If the bottle were dirty it might cause the gold to be precipitated. Exposing it to a strong light after being used will also cause precipitation of the gold. It is a good plan to prepare the solution in a concentrated form, and to dilute it down when required for use.

J. D. C.—A number of photographs of various sizes and descriptions have reached us from this correspondent, with the request that we will express an opinion as to their quality *at the price*, the prices being quoted. In reply: We must say that the work is certainly fairly good, especially when the low prices are taken into account. But the examples are stated to have been all, or nearly all, refused by our correspondent's clients, whose "ignorance," "meanness," and "shabby gentility," he thinks, do not permit them to recognise a good photograph. As many of the specimens sent us exhibit very palpable signs of long exhibition in the show-frame, we cannot help thinking that our correspondent has, under the circumstances of their rejection, scarcely acted a proper part in exhibiting the pictures.

Errata.—In Mr. R. Keene's article *On Landscape Photography* (page 440), in the thirteenth line of the second paragraph, first clause, for "past" *read* "earlier;" in the third line, third paragraph, for "toil" *read* "moil;" in the eleventh line, third paragraph, the passage reads "albumen dry plates came next—tannin, coffee, and beer plates—all useful," &c.; for "wet" in the first line, fourth paragraph, *read* "beer;" second line, sixth paragraph, for "makers" *read* "makes;" in the thirty-fifth line, second column, for "light" *read* "lights;" in the forty-sixth line, for "even" *read* "once;" in the forty-eighth line, for "production" *read* "subtle gradations;" in the fifty-third line, for "and" *read* "or;" in the sixty-third line, for "and" *read* "yea;" in the seventy-ninth line, for "clearness" *read* "*chiaroscuro;*" in the eighty-second line, for "arrived" *read* "aimed;" in the eighty-third line, "after this" *read* "series to;" in the sixth line, first column, page 441, after "acknowledge" *read* "yet no class," &c.; in the same line, for "use" *read* "useful;" seventh line, after "of" *read* "the"; for "photographers" *read* "photographer;" for "they" *read* "who;" in the twelfth line, for "limit" *read* "kind;" in the fourteenth line, for "upon" *read* "after;" in the next line, for "result" *read* "results;" in the twenty-first line, for "greater" *read* "great;" in the twenty-third line for "contiguous" *read* "with," and for "objects" *read* "object;" in the next line for "lenses" *read* "leaves," and in the following line for "robes" *read* "boles;" also in the twenty-eighth line, for "ream" *read* "record." The author's proof did not arrive last week before we went to press.

Received.—A. F. Genlain; "Photographer;" E. J. Chesterman. In our next.

Photographic Society of Great Britain.—The next monthly technical meeting of this Society will take place on Tuesday next, the 22nd instant, at eight p.m., at the Gallery, 5a, Pall Mall East.

Photographic Club.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 23rd inst., the subject for discussion will be—*The Effect of Coloured Media on Sensitised Paper.* The Saturday afternoon outing will be held at Hadley Wood; train to High Barnet Station. Meeting afterwards at "Old Salisbury Arms," High Barnet.

LONDON GAZETTE, *Tuesday, July* 15, 1884.

Adjudication.

Alfred Joseph Moores, West-street, Wareham, Dorsetshire, outfitter, boot salesman, and photographer.

JOURNAL OF PHOTOGRAPHY.

No. 1264. Vol. XXXI.—JULY 25, 1884.

EMULSIONS IN GELATINE AND ALBUMEN.

As we stated last week, the methods of emulsifying by precipitation are most suitable for employment in connection with gelatino-albumen emulsions, though it is not absolutely necessary to follow that plan. Our reason for giving the preference to the precipitation methods is that, owing to the comparatively small quantity of gelatine used—a large portion of the usual quantity being replaced by albumen—the emulsion is less easy to wash in the ordinary manner without loss. Owing to the solubility of the albumen in water it is obviously impossible to add that to the emulsion until after washing, as it would be removed with the other soluble matters. Moreover, if such a course were pursued, though the albumen would have the effect of rendering the emulsion more viscous, and so improve its power of holding the haloids in suspension, it would not in the slightest degree increase the strength of the jelly, but, practically, rather the contrary.

Though it is quite possible to wash in the ordinary manner or precipitate with alcohol an emulsion containing only ten grains of gelatine in each ounce, the extra care required militates against the employment of these methods; but, in the case of those who object to the precipitation processes, there is nothing for it but to accept the risk. We shall, however, confine our description to the processes with which we have succeeded best.

Of these the one we prefer is based on Mr. W. K. Burton's principle, though we have varied it in the details. We have adopted the following formula:—

1.

Gelatine	30 to 50 grains.
Bromide of potassium	300 „
Water	20 ounces.

2.

Silver nitrate	1 ounce (437·5 grains).
Nitric acid	1 minim.
Water	1½ ounce.

3.

Iodide of potassium	15 grains.
Water	1 drachm.

The three solutions having been made, we commence their mixture by cautiously adding, drop by drop, the solution of iodide of potassium to the concentrated silver solution, agitating after each addition. The first effect will, of course, be the formation of a precipitate of iodide of silver, but this is rapidly redissolved by the excess of silver nitrate until the solution becomes saturated. Under favourable conditions the full quantity of iodide may be thus added—that is to say, if the silver solution be sufficiently concentrated and its temperature not too high. However, the addition of iodide is continued until a permanent milkiness remains, when the remainder of the iodide, if there be any, is set aside until again required.

The bromised gelatine solution is now raised to boiling-point in the ordinary digester, and the silver added to it in the usual manner, and thoroughly mixed by shaking or stirring. When this is done the remainder of the iodide is added, and the cooking proceeded with by any of the methods in vogue. We prefer for our own part the ordinary boiling process, which is carried on to the verge of the blue stage if an emulsion of moderate rapidity only is required, or further in proportion. Or, after allowing the emulsion to cool, ammonia may be added, and the whole digested at a low temperature for an hour or so.

By the above plan of adding the iodide a very fine state of division is ensured as well as a higher degree of sensitiveness. The proportions of silver and haloids are so near the point of neutrality that very little trouble will be experienced in securing a rapid deposition of the sensitive precipitate; but if it should exhibit a reluctance to subside longer digestion with ammonia or longer boiling, as the case may be, will bring about an improvement. We find that an emulsion made in the evening will have invariably subsided sufficiently by morning to allow of the first change of washing water being made. Three such changes in all will prove ample.

The precipitated bromide having been thoroughly washed is transferred to a suitable flask or bottle; or, preferably, the washing may be performed in one of the conical precipitating or "parting" flasks, obtainable at any chemical glass warehouse. Into this is introduced 200 grains of hard gelatine, such as Heinrich's, previously swelled in distilled water, and sufficient water to make the bulk up to ten or twelve ounces. Heat is applied, and, as the gelatine dissolves, the flask is vigorously shaken to secure the thorough emulsification of the bromide. If, as will probably be the case, the bromide show a tendency to retain a slight granularity, it will be necessary to raise the temperature to about 200° Fahr., or even higher, and to keep it there, with occasional agitation, until the necessary degree of fineness is attained. It is for this reason—the probable necessity for the application of a high temperature—that the albumen is not added until the last stage of the operation.

While the above operations are proceeding, take the whites of the necessary number of eggs and beat them into a stiff froth without the addition of water, ammonia acetic acid, or any of the ordinary additions. For the above quantities of the ingredients four ounces of liquid albumen will suffice, or, roughly, the whites of four eggs. These having been converted into froth of such consistency that the vessel containing it may be reversed without any loss of albumen, the latter is transferred to a clean funnel of sufficient size, placed in a bottle or other vessel to catch the albumen as it gradually reliquefies, which it will do in the course of a few hours.

Returning to the emulsion, which we will now suppose to have gained the requisite degree of fineness: it is allowed to cool down to 90° or 100°, when the albumen is poured into it, and thoroughly mixed. All that now remains is to make the bulk up to twenty or twenty-four ounces (according to taste) to filter, and the emulsion is ready for coating.

Emulsion made in this manner sets rather more slowly than usual owing to the smaller proportion of gelatine it contains, but dries rapidly to a hard, glassy film. The films appear thinner and more transparent especially when dry than ordinary ones, but show no deficiency in the matter of density. Should still greater hardness be required, if the plates are to be long kept or subjected to the vicissitudes of travel, they may be passed singly, after drying, through a dish of good methylated alcohol carefully filtered. This will coagulate the albumen, and though it gives a little extra trouble the return is worth the outlay.

Such plates are moderately sensitive, giving, with half-an-hour to three-quarters' boiling, fifteen on the sensitometer. They develope quickly, owing, no doubt, to the comparatively-porous character given to the film under the action of the alkaline developer. The ammonia, indeed, seems to penetrate instantly, by its solvent action on the albumen, to the very glass itself.

Other methods of precipitation, such as Abney's, may be adopted if preferred, or the late Dr. Monckhoven's carbonate of silver and hydrobromic acid process may be employed, provided the albumen is not added until the bromide of silver has been fully formed. But the plan we have described in detail seems to be the simplest.

The hardness of such films appears to offer a fair prospect of their possessing better keeping qualities than some of the plates of which we have heard recent complaints; and if no impediment in the way of reduced sensitiveness should intervene we shall expect to see albumen films much employed in the future.

MERCURIAL INTENSIFICATION.

Among the numerous experiments made by the late Mr. Frederick Scott Archer, after his introduction of the collodion process, were those which led to his discovery of the bleaching agency of bichloride of mercury followed by the blackening of the image (thus whitened) by means of a solution of hyposulphite of soda.

In the course of time other agents than the hyposulphite were found to have the effect of darkening the chlorised image, and some one or other of these have secured the special favour of those who have had recourse to their aid in intensifying an image which was considered too feeble to produce a brilliant print. Among such agents we may mention iodide of potassium, cyanide of potassium (both alone and saturated with silver), sulphide of ammonium, and simple ammonia.

Each of the reagents named, and others besides, possesses its own special characteristics. For example: in the intensification of a negative of printed matter in which pure whites and intense blacks were required, the after-treatment of the whitened image, either by diluted sulphide of ammonium or solution of cyanide of potassium saturated with silver, followed as a matter of course, both giving extreme intensity, although the former imparts a deep brown colour by contrast with the purer black of the latter. Either of these, however, is apt to produce contrasts too strong to be pleasant in portraiture or landscape work. Diluted ammonia has, for photography of this class, assumed a position of high popularity, and is now employed to a greater extent than any other of the various agents by which the chlorised image is affected. It is not our intention to refer here to the characteristics of these agents or to classify the differences in the images that result from being subjected to their action, but rather to point out another which may with great advantage be added to their number.

In our *Notes and Queries*, in another page, one of our correspondents directs attention to the fact that a solution of sulphite of soda possesses advantages as an agent for employment in connection with bleaching by means of bichloride of mercury. The strength recommended is a saturated solution diluted to the extent of one-half. We have tried this method of intensification, and like it much. The tone is different from that obtained by either hyposulphite of soda or ammonia, and is of a pleasing character. For chemical reasons, into which we do not pause here to enter, there is no discolouration of the image even if it were suddenly transferred from the bichloride bath to the sulphite solution, the products of the decomposition being soluble in water.

Our trials of this intensifier have embraced both gelatine negatives and collodion transparencies, and we have nothing but high commendation of the system to make, so far as we have tried it.

COOLING AND VENTILATING.

The excessive heat experienced during the past few weeks has caused great discomfort to photographers generally, and it has also seriously interfered with the commercial working of several processes, more particularly those having to do with gelatine. In many studios, on some days, the heat has been really insupportable alike to the sitter and the artist; indeed, in some instances, to our knowledge, the former has been compelled to relinquish the idea of sitting for the time being immediately on the extreme oppressiveness of the studio being experienced.

Of course it is in studios of the old-fashioned type—those constructed with the largest possible amount of glass, and situated on the tops of houses—where the greatest inconvenience is experienced; although those of more modern date, with a minimum of glass, have also been excessively hot and uncomfortable at times. Much of the oppressiveness of the studio, however, might be prevented by a more perfect system of ventilation, by which the atmosphere may be kept in constant motion, and continually changed. It is the stagnancy of the air that, in a great measure, causes the oppressiveness. If it be kept moving, although it may be of the same temperature, it will be rendered much more agreeable. The mere opening of the windows in the sides and roof of the building is not sufficient to accomplish this, unless there is a strong wind blowing. To be effectual, under all conditions, some mechanical means of keeping the atmosphere in actual motion is necessary.

It is true that many modern studios are fitted with ventilators of some form or other, most of which, however, are intended to be worked by the wind, and when there is a sufficient breeze to keep them in action the effect they produce, in most cases, is very satisfactory. What is unfortunate in connection with all ventilators dependent upon the wind as a motive power is that in sultry weather—at the time when they are most required—there is not sufficient force in the wind to set them in motion.

In the Health Exhibition is to be seen a great variety of contrivances for effectually ventilating and changing the atmosphere of rooms and workshops, several of which are well adapted for ventilating studios and photographic workrooms, and require but a small motive power to drive them—a small gas engine of one- or two-man power being quite sufficient for a studio of ordinary dimensions.

We pointed out, a few weeks back, in an article entitled *Keeping Cool*, that the atmosphere in the basement of a building rarely exceeds a convenient temperature for the working of most photographic processes, whilst in the studio the heat may be quite insupportable. Now, if the cool atmosphere of the basement could be transferred to the heated studio what a comfort it would be both to the sitter and the operator! This is perfectly practicable, and the outlay for the necessary appliances is but small compared with the convenience and comfort secured. All that is required is to have one or other of the numerous forms of "blowers" or fans now in the market fixed in the basement of the building, with a six-inch common iron stove-pipe leading to the studio. Here two or three branches should be added, so as to deliver the cool air in different portions of the room near the floor. In the vicinity of the blower—though preferably in another apartment, on account of the heat evolved from it—must be fixed a small gas engine, several forms of which, suitable for our purpose, may now be had at a very moderate price.

It will now readily be seen that, when the blower is in action, a continuous current of cool and pleasant air will be driven into the studio, and thus render the atmosphere there far more comfortable. As the cold air in the basement would soon become exhausted, some means must be adopted to keep up the supply. This will be most effectively done by arranging the sponge cloths at the window, as we described in our previous article. If the studio be situated at a great distance from the source of cold air it will be found desirable to cover the leading pipe with felt or other non-conducting material; or the pipe may be constructed of wood, which, in itself, is a very good non-conductor of heat. The only drawback to a wooden tube—or rather spout—for the purpose is that the constant current of air, when dry, is liable to cause the wood to split, and so become leaky.

If the pipe be conducted outside the building it should be taken on the north side of it, and certainly be covered with the felt. Then, if a small stream of water be allowed to trickle on to the felt-coated pipe—near the upper portion—it will be kept moist throughout its entire length. The evaporation of the water will then not only keep the tube itself cool, but in some instances will reduce the temperature of the current of air within several degrees lower than it was when it left the basement. It is by no means necessary—or, indeed, is it desirable, on account of the heat from the engine—the apparatus should be fixed in the apartment from whence the supply of air is drawn; for it may be situated in any other portion of the building, by simply having a tube leading from the blower to the place from which the air is taken.

An objection may possibly be raised to this method of rendering the studio more comfortable during excessively hot weather on account of its being somewhat expensive. But we think this should not militate against its adoption, particularly when we see the lavish expenditure that is now very frequently made in decorating and furnishing reception-rooms and studios, which only conduce to outward appearances and not to the actual comfort of the sitter. There can be no question whatever that the more the sitter can be made to feel at ease, while a portrait is being taken, the more satisfactory will be the picture and the greater the credit to the artist. After all, the expense need not be greater than is often incurred for a large lens and camera that is rarely required. When once the apparatus is provided the cost of keeping it in action is merely nominal, as it will probably not exceed a penny or so per hour for gas.

Of course the plan here suggested of changing the atmosphere of apartments can be applied to many purposes in connection with photography besides that of cooling the studio. It might be utilised for combating the difficulty alluded to by Mr. Woodbury last week in working the Woodburytype and stannotype processes when it is not convenient to conduct the printing operations in the basement itself; also for keeping up a constant supply of cool air to the coating-room during the preparation of dry plates, and likewise in the manufacture of carbon tissue.

When we commenced this subject we intended to have said something about the apparatus that is now so largely employed for producing air of intense coldness, which may well be made available in many ways in connection with photographic operations, but space will not permit.

CAMERA PRINTING BY ARTIFICIAL LIGHT.

Equality in the illumination of the backing of a negative which is being printed from by the agency of a camera is an indispensable condition of success. In solar camera printing a well-made condenser supplies all the conditions of illumination in a manner that cannot be surpassed. So likewise in collodion transfer work, as commonly practised, does the uniform light of the sky subserve a similar purpose. But, as neither the sun nor the uniformly-lighted sky is available for the requirements of many who desire occasionally to produce prints from their negatives by the camera, the consideration of the best means of doing so by the aid of such appliances as are more or less abundant may prove of service, more especially to the amateur, who prefers to relegate this class of work to the evening.

Camera printing may be divided into several departments; but what follows is written after an investigation, as nearly exhaustive as possible, into the most effective and simple means of employing artificial light in the production of transparencies suitable for the lantern, the principles involved in this covering the whole ground of collodion transfers and enlargements upon paper prepared with gelatine emulsion.

If a negative be placed in a lantern competent to receive it, no difficulty will be experienced in visually reproducing it of any dimensions. None of the commercial lanterns of the present time, however, are constructed to receive other than *clichés* of dimensions not exceeding the capabilities of the condensers, which may be roughly stated as four inches in diameter; whereas we may desire illumination for a half-plate, a whole-plate, or even a size larger. In such a case the lantern fails. If one could command the services of condensers capable of transmitting light through an area eight or ten inches in circumference he would practically be in a position to undertake work of almost any description; but this not being the case in any save a few exceptional instances, we must have recourse to other means of securing illumination.

When a plate of ground glass is placed sufficiently near the source of light to be brightly illuminated, the rays from the lamp (which we may suppose to be one of the popular multiplex-wick class now so much employed in lantern practice) illuminate the centre in a degree so much greater than the sides as to interpose a serious obstacle to our special requirement—uniformity of illumination. This is corrected in some measure by the interposition of more than one plate of ground glass; but by the time uniformity has been obtained in this manner over a surface of sufficient extent, the energy of the light will have been weakened by absorption. When recourse has been had to the services of the condenser, in order to lessen the divergence of the rays of light, it is unfortunate that another evil is created—that of the representation of the flame as an ill-defined image upon the ground glass; and this proves rather more than the evil already mentioned. But when an objective of large aperture is interposed at a distance of its focus from the condenser, then we obtain perfect uniformity of illumination without loss of light.

The arrangements necessary in order to carry into practical effect this method of lighting so as to secure all its advantages are, first of all, a petroleum light of as powerful a character as possible, letting it be borne in mind that a more intense light is desirable for producing an enlargement than a reduction from any negative. The diameter of the condenser is of no special consequence; but it is of some importance that the object glass, especially the back lens, be large, in order that all the rays transmitted through the condenser be secured and passed on to the front. In the present case we have not so much to do with the image-forming capacity of the objective as its capability of permitting no light whatever to escape. A back lens of three and a-quarter inches in diameter, with a front lens two and a-half inches diameter, fulfil the conditions of lighting somewhat better than any other form of objective we have tried. The adjustment of these lenses to each other is such as to permit the larger of the two to be little more than its own diameter in front of the condensers. If the light emanated from a point, as in the case of the lime light, instead of, as in the modern petroleum lamp, being characterised by magnitude, then an objective of smaller aperture would suffice.

The light from an objective of this class is emitted at only a slight angle of divergence, and when concentrated upon a plate of ground glass of about eight inches square it renders it intensely luminous when viewed from the opposite side. But it is necessary that the ground glass be scrupulously clean in the sense of being free from grease; for a spot of grease, by rendering that portion semi-transparent, would prevent it from fulfilling its functions as a radiator. A sheet of roughly-grained glass may sometimes be interposed with advantage between the fine glass and the light, at a distance of about an inch from the former; but if the finely-grained glass be of good quality, and be cleaned to perfect greyness, this should not be required.

The frame containing the negative is placed in front of the ground glass—the nearer to it the better, so long as it is beyond the plane of sharp focus—and to the negative thus situated the lens of an ordinary working wet collodion camera is directed. If the image be required to be of the same dimensions as the negative, then the camera must be extended so as to have its focussing-screen removed from the lens a distance equalling twice its focus. As a type of lens known to most photographers, we might mention the No. 2 *carte* of Ross or the No. 113 of Dallmeyer as belonging to the class that will, with full aperture, cover a square for the lantern in an excellent manner without the necessity for any diaphragm being employed—no small advantage when working with an artificial light of the character now in question.

When all the arrangements are complete, and a wet collodion plate is exposed, a good image will be impressed in an incredibly brief length of time—a period measured by seconds rather than by minutes. With certain negatives an exposure of fifteen seconds will prove ample; with others the time will have to be increased or diminished according to circumstances. An enlargement of nearly two diameters necessitated an exposure of a minute and a-half, the developer being ferrous sulphate, fifteen grains to the ounce, with a minute trace of tartaric acid.

Instead of transmitting the light through ground glass an equally even illumination may be obtained by directing the diverging cone of light from the lantern upon a sheet of white card or paper, in front of which must be erected the frame containing the negative. In this case the illuminating lantern and the camera must be placed at an angle to each other, both being directed towards the sheet of cardboard, which should be at an angle having regard to each, and so situated to the negative as to receive all the light emanating from the lantern without any falling upon the negative. But the ground-glass method is that for which we entertain a preference.

A PRINT-WASHING TROUGH FOR *CARTES* AND CABINETS.

There are throughout the country dispersed among the workrooms of photographers, professional and amateur, as many different forms of washing troughs as there are days in the year. Though, on the one hand, ever and again we have new forms introduced, many of them strong in just claims for originality and usefulness, yet, on the other hand, a large number of photographers content themselves with nothing more elaborate than a water-tap and a dish. Further than this, paradoxical though it may sound, we say without fear of contradiction that the latter arrangement need be no less effective than the most elaborate and costly contrivance in the world; it requires, however, so as to deserve this encomium, to be used with great attention and worked with brains. Too often, we believe, is it the case that prints are put in a dish, the tap turned on, the water left running till morning, and the prints then taken out under the impression that they are washed—wasked, when, perhaps, the prints in the middle of the heap have never once changed their place for twelve hours! When, however, the prints are taken out one by one and placed in fresh water, and the process repeated from time to time, the dish system is equal to any other.

This is so laborious a process, and requires such unremitting attention over a considerable period of time, that mechanical or automatic means have been devised and been in use for many years. There are mechanical contrivances which require attention for a limited time, and there are automatic machines which need no attention at all when once they are set in action; and this class, if efficient and economical, is naturally the one to suit the generality of photographers. A print-washer that needs no time to be devoted to it nor attention given while in action—that simply requires the prints to be put in and a tap turned on with a certainty that a thorough washing will have taken place when the prints are taken out a few hours later—is the machine that will appeal to the photographic public. Many machines claiming to possess these qualifications have appeared, and which do exhibit points of excellence; but most of them leave something to be desired. We have, however, seen one, intended for *cartes* and cabinets, in which so many good points are included that, with the permission of the gentleman who designed it, we give a description of it and details of its construction. It is merely an adaptation of a very old pattern, but it avoids several of the defects which characterised the older arrangement.

One of the oldest forms of automatic washers was a trough or dish with a row of jets for the admission of water at the top, and a syphon, connected with an opening at the bottom, for drawing off the water when the trough was filled. It was early seen that a system for drawing off the washing water at intervals was far more effective in speedily ridding the prints of hypo. than the mere flushing with a continuous flow. This is easily proved by the oft-described experiment of putting a cupful of some coloured liquid in a dish of water, turning the tap on to it, and allowing the surplus to overflow, or connecting it with a syphon to draw the whole off when full. In the former case a distinct trace of the colour would be visible after the lapse of a considerable length of time, while in the latter the colour would be almost all discharged after the first emptying of the vessel.

The original form, then, of the syphon washer was a circular trough (first, we believe, made in zinc and afterwards in earthenware) with straight sides, a false bottom of perforated zinc to prevent the prints being drawn into the exit pipe by the outgoing current, and a ring of lead piping perforated with numerous small holes to send the water as a kind of spray on to the prints. In action it was found—first, that though the water was changed at intervals, much of the efficacy of the change was lost by the bulk of the prints adhering together in a mass; and, secondly, that a certain number of the prints, when the trough was empty, attached themselves to the sides and remained there all through, while many others, as the water drained away, became bent and their texture broken by sinking into the sharp angle at the bottom formed by the junction of the latter with the sides. Hence every morning (presuming the pictures to have been washing all night) there was a large percentage of prints spoiled by being permanently marked with a crease, or torn in their removal from the angle.

To remedy the defect of the prints collecting in a heap many devices were tried, and some machines were made with a jet placed at various angles in lieu of the series of spray jets, with the object of causing a cleansing action upon the prints by giving a rotary motion to the water in the trough. A brief inspection shortly after the machine was set in action would apparently show the object to have been attained; but, on a close examination, it was to be observed that after a while they would all clog together in a mass and so remain for hours.

To avoid the second evil—that of the prints collecting in the angle and becoming torn or creased—many plans have been tried, but none, perhaps, simpler or better than that adopted in the particular trough to which we are referring, which consisted simply in having it made without any angle whatever. A trough was constructed entirely of zinc, plain and perforated, and shaped exactly like a huge saucer, so that, no matter what position the prints were in during the periodical running-dry of the apparatus, they always fell upon an almost flat surface, the trough being made of large size, and shallow.

The chief difficulty next met with was turning the water among the prints so as to ensure their separation and the penetration of the fresh water among them. A spray action, as we have explained, did not cause them to separate. A jet set at an angle to give a rotary motion sent them in a clump into the middle of the trough; while, if a second jet at a different angle were used in addition, one or other, however opposed, would obtain the mastery and send a cluster of prints either to the side or again to the middle.

This difficulty, after a large number of forms and positions of jets had been tried, was overcome simply enough by increasing their number and setting them at a particular angle, so that at last what was practically a perfect syphon washer was designed. The prints were kept in continuous motion the greater part of the time, they were constantly changing their positions, and when they were left to drain were in no danger of creasing; in fact, so far as the syphon-washing principle was involved, it would be difficult to suggest an improvement.

The verbal description we have thus given would enable anyone to construct a trough; but to provide increased facility we will, in our next issue, supplement our remarks by giving a scale drawing, with a description of those other minor details an acquaintance with which goes so far to render the use of this or any piece of apparatus a real success.

The fine front of the National Gallery, in Trafalgar-square, is at present being disgraced by a corrugated iron shed now in course of erection at one side of the entrance. We had for the last few days been puzzled to account for the presence of this shed; but the following, from a daily newspaper, throws light upon it, and assigns it a position among our metropolitan photographic studios:—"A novelty will soon be introduced in the National Gallery. Of all the great European galleries ours was the last to recognise the presence of the photographer. The collections of Berlin, Cassel, the Hague, Madrid, and even Petersburg, were photographed in many sizes, and might be bought all over the continent, while our art treasures were only known to strangers by copies or engravings. Latterly photography was tolerated, yet it was only tolerated. But few pictures were done, and the sizes were small and the results

SUPPLEMENT TO THE BRITISH JOURNAL OF PHOTOGRAPHY, JULY 25TH 1884.

R. L. MADDOX, M.D.

INK-PHOTO, SPRAGUE & Co LONDON.

unsatisfactory. This reproach will no longer be heard. On the flagway, between the railings and the front of the building, a shed is being erected in Trafalgar-square which will be fitted up as a photographer's studio. The required canvases will here be taken with the advantages of a proper position and a good light. London is following the example set a dozen years ago by Dresden. In many of the other galleries the photographs were originally taken from the pictures as they hung upon the walls, and thus the copyist laboured under disadvantages which were evident from his results. We shall, no doubt, have a good reproduction of the collection, and, it is to be hoped, at moderate prices."

It is but a short time since we chronicled the feat of liquefying oxygen—one of the "permanent" gases; and now it is said that the production of liquid oxygen as an article of commerce is not only brought within the range of practical chemistry, but is a very probable occurrence. M. Cailletet has discovered a new method of bringing about the liquefaction, which is of so easy a nature, he states, that it may be looked upon as one of the simplest operations of the laboratory. He finds that *formene*, when slightly condensed and cooled in boiling ethylene under atmospheric pressure, is resolved into an extremely volatile, colourless fluid, which, in again passing into the gaseous state, yields a degree of cold sufficient to liquefy oxygen, thus rendering comparatively easy and simple the process which first required a costly and elaborate series of apparatus.

Nevertheless, until liquid ethylene also becomes a commercial product it is rather idle to speak of oxygen being so, and the manufacture of liquid oxygen for the lime light is, we should be inclined to believe, far more distant than some enthusiastic vaticinators would have us believe. Compressed oxygen may become the usual mode of carrying the gas to the lecture room; but the more likely commercial enterprise will be the making of the gas on a large scale at a cheap price for the purposes of storage or compression. Every method likely to bring about such economy will be hailed with much satisfaction by many photographers and lantern exhibitors. Many processes have been devised, and we have heard a great deal at one time or another of companies formed for the making and storing of oxygen under certain new patents. At present it is as dear as ever it was. The latest idea in this direction is that of M. L. Troost, who, in a note to the *Académie*, described a new principle to work upon in making oxygen. He stated that pure oxygen and the oxygen of the atmosphere are capable of passing through a tube of silver heated to 800°, while a mere trace only of nitrogen penetrates the metal. Upon this principle M. Troost suggests that pure oxygen may be obtained.

In the International Inventions Exhibition, to be held next year, there will be a special department for photography under the head of Group XXIX. According to the schedule just published the following will be the arrangements:—"Class 159. *Processes and their Results.*—Methods of gelatino-bromide plate-making, apparatus for making emulsion, apparatus for separating the sensitive constituents; coating, drying, and packing machines; emulsion and other processes; printing processes—silver, carbon, Woodburytype, platinotype; gelatino-bromides, collodio-chloride of silver, &c.; apparatus for washing, &c., prints and negatives; methods for making photographic lantern slides.—Class 160. *Apparatus (excluding lenses).*—Cameras, shutters, changing-boxes, slides, tents, lamps; apparatus for making enlargements and for microphotography. Class 161. *Application of Photography to various Purposes, Typography, Ceramics, Relief-moulds, &c.*—Method of producing printing surfaces; photographic enamels, photographic printing on pottery; photographic reliefs; use of photography in self-recording apparatus in scientific observations, &c. In addition to the special place for photography found in this group it comes in for mention also in Group XXVIII., under "*optical*" heading as "photographic lenses," and in Group XXV. under "*military equipment*" simply as "photographic."

The action of oxygen upon pyrogallic acid in solution is familiar to dry-plate workers. The rapidity with which it absorbs oxygen, shown by the red discolouration when rendered alkaline, and the non-colouration when acid, are well known by the state of the developer after use in the one case, and of the acid store solution in the other. It has been stated that tannin is also acted upon by the oxygen of the atmosphere; but, according to M. Antony Guyard, this is an error. He has made a long and elaborate series of experiments which conclusively prove that oxygen has no action whatever upon dilute solutions of tannin; but when rendered alkaline purified air acts, on the contrary, with great energy. This is a very interesting fact, and links tannin still more closely to gallic and pyrogallic acids. The same writer points out a very simple reaction for separating tannin and gallic acid, which are so often found together. Lead acetate acidulated with acetic acid will dissolve lead gallate, but fails to take up the slightest quantity of lead tannate; and so the separating of the two may evidently be done very readily.

Mr. Herbert McLeod, who has invented a simple sunshine recorder — which he described, but did not exhibit, at a recent meeting of the Physical Society—writes to say that the account published is in error. The instrument consists, in his own words, of a camera fixed with its axis parallel to that of the *earth*, and with the lens northward; and there is placed opposite to the lens a round-bottomed flask silvered inside. The light reflected from the sphere passes through the lens and acts on the sensitive paper. This is a very different thing from the description given in the papers.

An ingenious new glass tap is described in one of the foreign chemical journals. A glass tube is bent at right angles and its shorter limb passed through a cork, which is then fitted into the place where an ordinary tap would be placed (there are glass bottles to be had fitted with tubulures near the bottom for the purpose of inserting a tap). When fitted, there is simply a bottle with a piece of glass tube projecting upwards from the bottom, its contents being connected, of course, with the external air. All that is necessary to do in order to withdraw some of the contents is simply to turn the tube on its side, when the liquid will flow out as soon as the end of the tube is as low as the level of the liquid within the vessel.

Ether will dissolve chloride of gold, chloride of iron, nitrate of uranium, bichloride of mercury, &c., &c.; but if an etherial solution of any of the salts be shaken up with glycerine, the latter liquid, which dissolves them better than ether, will extract almost the whole of the salts and form a glycerine solution in lieu of the etherial.

DR. R. L. MADDOX.

The name of the gentleman whose portrait we give in the present number is familiar to most of our readers as having been connected with photomicrography for upwards of thirty years past, and as the originator of the gelatino-bromide process, the first description of which appeared from his pen in the pages of this Journal in 1871.

Dr. R. L. Maddox, after a voyage round the world in 1839-40 in search of health, spent many years abroad practising in an official and private capacity, but had eventually to renounce the arduous duties of his profession from constant suffering of a very painful nature, which has extended over half-a-century. He had early taken up the subject of microscopy as connected with his profession, and had translated Dr. Dujardin's manual at the time that Quekett's *Treatise on the Microscope* appeared. Owing to the impossibility of arranging for the use of the beautiful plates of Dujardin's work, the translation was never published.

Being obliged to return to England Dr. Maddox employed himself in trying to extend the labours of others by combining photography with microscopic research, and in this path was so far successful as to be the recipient of two medals, and for his various writings on this and microscopical subjects he was elected an Honorary Fellow of the Royal Microscopical Society.

About the time of his introduction of the gelatino-bromide process Dr. Maddox was carrying on a series of examinations on the living organisms found in the atmosphere, and which necessitated prolonged and tedious work with the microscope, amounting sometimes to sixteen hours in the day. In his method he differed entirely from those who had preceded him, and this has been made the basis of further and most extended researches by others, especially by Dr. Douglas Cunningham and his friend Dr. Miquel, of the Observatory of Montsouris, Paris. Dr. Maddox used an apparatus of his own invention—the "aëroconiscope"—a kind of multiple funnel set up as a vane. The wind traversing this instrument deposited the organisms on a thin cover-glass duly prepared for the purpose. The organisms were then cultivated, and many of them carefully figured, the results being published in the current Monthly Microscopical Journal.

Of the gelatino-bromide process we need scarcely say more than that its present high state of utility has been brought about by the labours of the many, and Dr. Maddox may justly be proud that he closed his paper on the process with the hope that he had given another handle to the photographers' wheel, which has indeed, without restriction, been turned to their common benefit.

He gave much of his time to microscopic drawing, as is attested in the work of the late Dr. Parkes on *Hygiene* and Dr. Nayler on *Skin Diseases*, and other authors; but his coloured drawings of many of the *Diatomaceæ* under reagents, and his figures of the ferments in the deposits of beer, &c., have, we believe, never been published. Worn down by much suffering, he was again obliged to reside abroad for a considerable period, and renounce his favourite pursuits; but since his return he has devoted much of his time to them, especially in the endeavour to photograph the *Bacteria*—some of the minutest living entities, which require both skill and patience for their reproduction by photography.

Dr. Maddox was always ready to impart any information he might possess, holding that the claims of Science, for her advancement, were—"if freely ye have received, freely give."

The accompanying portrait was taken specially by Mr. J. Thomson, F.R.G.S., 70a, Grosvenor-street, W., and is considered an excellent likeness.

PRINTING STAINS ON GELATINE NEGATIVES.

There are few photographers, either amateur or professional, who have not suffered more or less from their negatives becoming stained and spotted by contact with the silvered paper. This is especially the case with those who sensitise their own paper—and professionals are therefore, perhaps, greater sufferers than amateurs—one essential element in the production of these spots and stains being damp, which, for obvious reasons, is not present in the ready sensitised paper.

Perfectly dry silvered paper has apparently no injurious effect on a gelatine film. I discovered, on taking down a printing-frame for use rather early in the present season, that a negative with a half-printed proof in contact had inadvertently been stored away during the whole winter—probably for a period of four or five months—without having produced a single mark. On the other hand, some negatives I sent to a professional printer, and from which no more than two prints were taken, developed these objectionable spots within a week or two after they were returned to me, and caused me to arrive at the determination that I would do my printing at home in future.

The fact of a negative having been collodionised or varnished appears to be little or no protection in the long run, as, though the formation of the spots may be delayed for a time, they are certain to appear eventually if a negative be much used and with slightly damp paper. I saw a suggestion a short time back as to the employment of thin, translucent paper between the negative and print as a preventive. This seems good, but better still would be a transparent gelatine film or thin sheet of mica. The former could be easily changed when stained or spotted; the latter would possess little liability in that direction.

Prevention is, of course, better than cure; but where the malady already exists it is useless to talk of preventive measures. But, unfortunately, of all the curative measures hitherto proposed not a single one has proved effective in my hands except, perhaps, in very mild cases. So far as I am aware all the substances recommended for the purpose of removing the spots do so by virtue of their action upon silver and organic silver compounds, and their action takes place, therefore, on the negative image as well as upon the stains. It follows that where the defect is very pronounced the application of any of the usual "remedies" will do as much harm to the image as it does good from another point of view.

I think, however, I have found a remedy which acts without injury to the negative image. It consists in "chlorising" or whitening the whole image and redeveloping, when, by transmitted light, the spots will be found to have entirely disappeared, though they are still visible on the surface. I made the discovery in the course of some experiments in mercurial intensification, when, having selected for the purpose some negatives which had become useless from silver spots, I was astonished to find that after treatment the defect had entirely disappeared. However prominent the spots may be in the negative the effect appears to be rather caused by a change of colour than by the addition of any considerable quantity of silver to the film; at anyrate, when the whole of the deposit is converted, as I have described, into a new state and then reconverted into a printable image, the difference in the transmitted colour and density of the spots disappears. It is only fair to say that I have not had an opportunity of trying the remedy on any *very* bad cases, but such as I have treated have been bad enough to be useless for printing.

In addition to treatment with mercury followed by ammonia, I have succeeded with chloride of copper and redevelopment with ferrous oxalate; but, no doubt, any method based upon the same principle will answer equally well. I give the cue, leaving it to each individual to select his favourite method. The treatment with mercury need not necessarily result in intensification; while, if the want of permanency of the mercurial image be an objection, chloride of copper or ferric oxalate may be used.

H. Y. E. Cotesworth.

LIME LIGHTING.

I notice a discussion is proceeding in the columns of the Journal relative to the merits of various forms of gasholders, the question seeming to be whether india-rubber bags or iron bottles are preferable. I suppose that the tank gasometer may be considered shelved, as the water required for its use is one source of trouble, and the weighting up a still greater nuisance, to say nothing of the size of ten and twelve feet receivers—about the quantity required for a two hours' exhibition by a triple lantern.

Having had considerable experience in the United States with cylinders of large size, I must say they seem to possess advantages over everything yet devised for containing the gases used for the lime light, and, except by the grossest want of care, stand pre-eminent for safety.

I understand in this country that in the bottles used the gas is compressed as high as 800 lbs. on the square inch, and I have noticed also that the valve is unprovided with a stuffing-box. The pressure seems extravagant to an American, whose cylinders are large enough to contain from 15 to 100 cubic feet at 225 lbs.

The sizes favoured by lanternists are those holding 25 or 40 feet at that pressure, which frequently are pumped in to 100 lbs. by the operator, who uses a pump for the purpose of a portable nature, costing $40 (£8). It is very ornamental, has a heavy fly-wheel, oscillating barrel, handsomely nickelled, pressure-gauge, and exquisite inlet and outlet valves. At such a low pressure no water is required to keep the barrel cool, and the operation is a quick and easy one. Another pump is sold which will compress up to 300 lbs. by the aid of a long lever when portability is required, or, if stationary, by crank and double fly-wheels. The former costs $65 (£13), the latter $100 (£20).

I have used all these pumps by hand and power, and give results of the time taken to charge a twenty-five-feet cylinder:—

Oscillating pump	100 pounds,	10 feet,	20 minutes.	
Lever pump	225	,,	25 ,,	45 ,,
Crank pump (hand)	225	,,	25 ,,	32 ,,
,, ,, (power)	225	,,	25 ,,	25 ,,

A water vessel is preferable with the lever pump, though not absolutely necessary; with the crank form it is an essential. The barrels stand a test of a thousand pounds, and the apparatus is almost indestructible.

The retort used for oxygen is a continuous-action one, made of wrought iron. It has to be connected with a wash-bottle and receiver. The hydrogen is taken direct from the main, except in case of power being used, when a small gasholder is required to keep the pump regularly supplied.

Ninety-nine vessels out of every hundred are filled by the various calcium light companies distributed over the large cities of America. They charge eighteen cents (9d.) a foot for oxygen, three cents (1½d.) for carburetted hydrogen, and twenty-five cents (1s.) per week hire for each cylinder, irrespective of size. When returned the unused oxygen is allowed for at purchase rate. The purchaser pays carriage. It is nothing unusual to send cylinders a thousand miles; and, although the valves sometimes get slightly injured and the glossy paint is soon defaced, no trouble or delay is experienced in getting them in time.

The light is exquisite, and now that the problem has been solved (at least, so I gather) of its regulation, it is only a question of time before the bag is ousted, with its attendant pressure-board and weights.

Has it ever occurred to any limelightist to inquire into an explosive source that seems to have been overlooked—that is, the vapour given off from the hydrocarbon used in joining the seams of the bags? I know of two instances where a light was applied to discover leaks. One bag exploded with a terrific report. It was a small one holding only three feet, had been allowed to remain neglected, and so got hard and stiff. When tilled leakage was noticeable, and a light being used to discover the source caused its destruction. The other case was similar, only it happened with a large bag, which merely burned up. Both were filled with oxygen.

I feel sure Mr. Lewis Wright will never use bags when he sees a pair of large cylinders doing their duty. Mr. R. A. Proctor's manipulator was not fit for his task, and was probably the man killed in one of the Western theatres during the performance of the "Lights o' London." As he had transferred and pumped hydrogen into the oxygen receiver—had the error pointed out to him, and yet lit up!—whose fault was it? Regarding cases not being reported: they are, but two lines is often the space given, instead of half-a-column and likely a leader as well. A man who tried to light the oxygen first in an Ohio theatre was sent to prison; he was drunk at the time. I notice men here get one shilling and sixpence a show. The pay in America is one dollar (four shillings).

During the last twenty years the lantern has been advanced from a toy to a scientific instrument; but it is yet far from perfect. It seems to me the aphengescopic principle could be more fully developed if the light were stronger. I remember a lantern by Chadburn, at the Polytechnic, that showed *cartes de visite* an enormous size. The jet was very noisy I will allow, but of great power. Why do not some of our scientists turn their attention that way instead of worrying about safety-valves? Hemming and Tate's are the most perfect I know of; but the check on the flow of gas is a downright nuisance in every form.

Really, little remains to be written on lantern history, as it is so fully and ably treated by Mr. Samuel Highley, in Cassell's *Technical and Popular Educators;* and, if republished, would form the most perfect manual extant on the subject.

The lime has great influence upon the light. Those used in the United States are very long, the hardest magnesian limestone is used, and they fit into cups—a better arrangement than the wire—dispensing with the hole in the centre, which is troublesome to drill and causes innumerable splits to occur.

J. Simpson Tomkins.

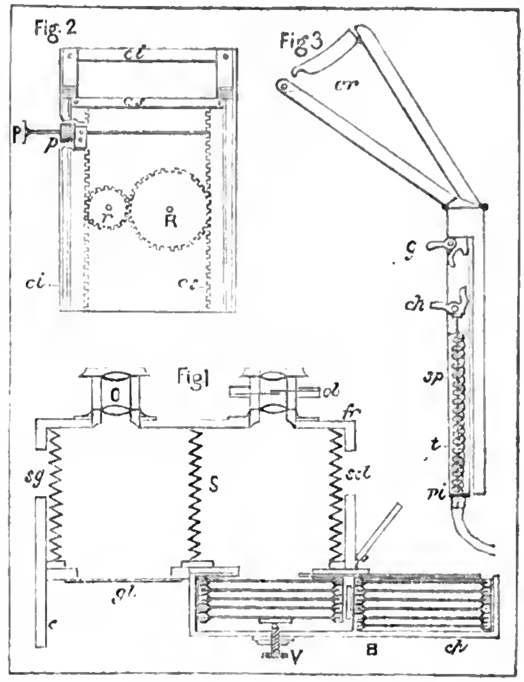
APPARATUS FOR INSTANTANEOUS PHOTOGRAPHY.

Professor Herman Fol has lately described in *La Nature* an instantaneous camera, with repeating backs, which he designed some time ago, but had not before published. He points out the usual difficulties attending the use of ordinary apparatus, and the loss of time between exposing and focussing, which, as he observes, causes the loss of many subjects. This latter difficulty, he states, has been surmounted in three ways:—First, by the use of lenses giving all objects in focus at once, and thus need no focussing. This plan he objects to as requiring longer exposures, giving an image that is neither quite sharp in any one plane nor in correct drawing. The second plan is that of Messrs. Muybridge and Marey. It requires the apparatus to be placed *in situ* beforehand, and the object driven between lens and screen—a plan possessing obvious objections, and suitable only to a confined class of subjects. The third plan is that employed by himself—a double camera with twin lenses—its principle having been, as he says, adopted long ago, though its application seemed to him to have been quite neglected till recently. Professor Fol thinks the later experiments with the same apparatus no more successful than the first, on account of the want of steadiness. Further: he says most of these apparata take only very small plates—M. Marey's gun, the photographic opera-glass, and M. Enjalbert's photographic revolver—and, the image being necessarily still smaller, they are practically useless.

His new apparatus, which he terms the "repeating photographic gun," had been invented before the publication of Messrs. Muybridge and Marey's mode of procedure, and has been in actual use over two years. It takes plates twelve centimetres by nine, although utilising the centre of the field only, and requires scarcely any adjustments in working it. Below we give detailed drawings and sections. The objectives are Steinheil's anti-planets two and a-half centimetres diameter and fourteen and a-half focus, capable of covering a plate thirty-two centimetres long. Of this we may say that a plate whose length is more than double the focus of the lens cannot cover sharply all over.

The shutter is a spring one with pneumatic release, and is made of two metallic plates, with apertures which pass in contrary directions between the places of the objectives where the diaphragm is usually placed. The exposure can be varied at will from the one-eightieth to the hundred-and-twentieth of a second.

The camera is composed of a bellows (*s*, *fig.* 1) completely divided into two spaces by a light-proof partition. This bellows Professor Fol had to construct for himself as one could not be purchased. Some pieces of cardboard, thin black silk, and a piece of black glove-kid were all that was needed. The left half of the bellows (*s g*, *fig.* 1) forms a compartment in which the left-hand lens throws an image on the ground glass (*g l*). The right bellows (*s d*) restricts the size of picture formed by the lens carrying the shutter, this image being identical with the first, but received upon a sensitive plate contained in the box B. A small board



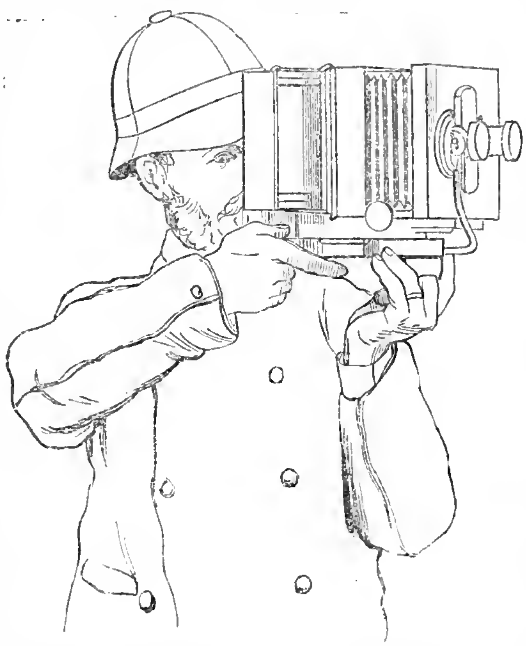
(*f r*) in front carries the two objectives, and has attached to it the front part of the bellows. A broad frame (*c*) carries the ground glass and the plate-box, and serves also as a place whereon to fasten the back part of the bellows. Focussing is performed by an apparatus described further on.

The plate-box is sufficiently large to contain a dozen plates in two lots of six each. Every plate is fixed in a little wooden frame backed with a piece of thin tin plate, which thus keeps all light from passing through. The two lots of plates are kept from one another by means of an incomplete screen, allowing room enough on one side, and on the other space for the frames to slide over one another. If, now, this box for twelve plates has only eleven, there remains an empty space, so that by inclining the apparatus the eleventh frame of one lot may be made to slide upon the other. When a plate has been exposed all that is needed to re-set the apparatus is simply to set it upright and then incline it towards the right, so that the exposed plate passes into the right compartment. If the apparatus be now turned so that the objectives point down, and the whole is inclined to the left, one of the right-hand plates will pass over to complete the left-hand set. Before each exposure it is desirable to tighten the screw (V) a little so as to press the foremost frame against the ledge of the box in order to make the image precisely correspond with that in the focussing half. By repeating these movements the whole dozen plates can be exposed without possibility of confusion, opening the box, or allowing light to gain admission except during an exposure.

The exposures complete, a metallic plate is pushed within, and separates the interior of the plate-box from the right-hand compartment, whence they can be removed, and the whole apparatus brought to within 13 centimetres by 16 by 24. Of course there is nothing to prevent it being furnished with twenty-two or thirty-three negatives.

The focussing is done by two frames of metallic rackwork in the under part of the apparatus (*fig.* 2), one carrying the front board (*ci*), while the other (*cs*) slides upon a groove of the frame. The two frames work together by means of a side button (P), terminating a rod which carries two grooved cylinders (*p*), the grooves working into a rack in the side pieces of the metallic frame (*ci*). The frame *cs* is worked by a horizontal wheel (R) with a vertical axis ended below by a knob, which is held in the left hand, and which helps to support the apparatus like a gun. A slight turning of the hand in one direction or the other suffices to give rapid motion to the front by means of the large wheel (R). A little toothed wheel (*r*) serves to transmit the motion of the large wheel at the side opposite to the frame, ensures its easy movement, and obviates all lateral displacement.

During use the apparatus is supported by a rest like a gun-stock, composed of four laths hinged so as to turn entirely over upon itself. The front part incloses a cylindrical tube (*t, fig.* 3), in which a piston works pressed by a coiled spring. In holding it this spring briskly pushes the piston in front and causes a compression of air in the tube, which is transmitted by the little india-rubber tube (*p i*) to the shutter, and effects its disengagement. To hold the spring it suffices to draw in front the piece (*c h*) until it catches the hook (*g*). A pressure of the finger upon this last causes the instant release of the shutter.



"The mode of using the apparatus as described is most simple, and in actual practice Professor Fol has obtained pictures of a variety of difficult subjects—pigeons flying, girls playing with skipping-rope, boys at leap-frog, &c., &c., and he quite thinks that his new apparatus will form a most useful complement to those of Messrs. Muybridge and Marey.

PHOTOMICROGRAPHY AT THE HEALTH EXHIBITION.

No. II.

At the same table will be seen a beautiful little aëroscope connected with chronometric clockwork, which causes the rotation of a leading central screw attached to a frame that carries a piece of glass like an ordinary microscope slide, divided by lines into twenty-four hours and one extra. This is smeared with a sterilised viscous material and turned face down, so that when the experiment is begun the extra line corresponds with the aperture in the funnel opening beneath. The clock, being allowed to act for an hour, brings the line of the next division into registration at midday. The instrument being attached to an aspirator and air-meter, the air is sucked through the funnel, leaving the germs, bacteria, fungi, &c., on the glass as it traverses centrally across the orifice of the funnel at the rate of an hour between each graduation. This is a most useful and ingenious instrument, but rather costly.

There is another of a somewhat similar function, consisting of a bell glass inverted over another with a ledge, which can be filled by vaseline, glycerine, or oil to render the inner space air-tight, whilst a disc divided into separate spaces and covered with a sticky material is made to rotate by a drum clock beneath, so that the divisions are brought opposite to a long slit ground out in the upper part of the bell glass for the air to enter. At the conclusion of the experiment the glass plate is removed and examined by the use of the microscope, though the naked eye can detect differences between the hourly deposits.

There is another small nickel-plated aëroscope attached to an ordinary water aspirator; a portable aspirator, consisting of two large glass jars, for drawing over a moderate but definite quantity of air; and an ordinary water aspirator; also a mercurial one for the drawing over fractional portions of air. Likewise on two pillars at the corners of the table are the modified forms of the Maddox aëroscope, as used at sea and on land. There are different forms of sterilising apparatus both for hot and cold filtration, and several flasks with readily-alterable fluids which have thus been sterilised, and remain perfectly clear. There are some useful little glass culture cells—a modification of Van Tieghem and Lemmonier's cell —and delicate pipettes for infecting the droplet of sterilised fluid placed on the thin cover glass for microscopic examination uner culture.

To the exhibits is added a very valuable list of disinfectants, ad such articles as prevent the rejuvenescence of bacteria in readily-putrescible fluid, the biniodide of mercury heading the list; 0·25 of a gramme preventing the putrescence of *one litre* of neutral bef broth—a thousand times less in weight than what is required of crystallised phenic acid. This list alone suffices to particularie Dr. Miquel's patience and industry. (See *La Semaine Médicale* fr 30th August, 1883.) It may be stated that the mildews, which are constant in the air, interfere largely by their rapid growth in the culture chamber if the sterilised liquid be at all acid; hence care is needed to neutralise, or even render slightly alkaline, the liquid in use. Dr. Miquel has raised an important point, *much overlooked*, as to the death and reviving points in different liquids, and the same liquids at different degrees of density. There are also M. Certes' exhibits of water analysis by colouring the different living organisms.

At the same table are other exhibits, and notably some microscopes by Verrick, and large model microscopes by Nachet, accompanied by a photomicrographic camera. This differs from any we are acquainted with, in that it contains a side tube carrying a prism, used in the examination and placing of the object, and which allows of the prism being withdrawn out of the field prior to exposure, so that a person seated at the side can manipulate the apparatus with ease. The camera is of a fixed length and carries at the side the focussing-rod, connected by a pulley and cord with the fine adjustment. We rather object to the position of the focussing-rod, which, like that made by Siebert, we fear may be somewhat in the way.

We must not longer linger over the interesting objects of this exhibit, which we heard a gentleman say was one of those of the greatest interest in the Exhibition, but pass to the table of M. Pasteur—a name too widely known and appreciated for us to attempt to further eulogise. His valuable contributions to the study of vinegar formation by aërial germs; his work on beer, with studies of the different yeast ferments, and the part they with other more minute organisms play in giving various flavours to beer; his mode of heating wine (Pasteurising); his extensive studies on the silkworm disease; his experiments on the cholera of fowls; his efforts to lessen the dire mortality in animals from cattle plague, by the inoculation of a modified form of the virus—all commercially attest to his genius and the value of the microscope. A list is given of the number of animals vaccinated, compiled from the combined labours of his assistants—Chamberland, Roux, Thuillier, and others.*

The above will suffice to induce those interested to examine the various forms of apparatus used in the culture and preparation of sterilised fluids. Among numerous flasks filled with such liquids, notably there stands a large flask—one of historical date—with which he confronted Baron Leibig's theory of fermentation, and showed that the minute living yeast cell was capable of inducing molecular changes in inorganic media. In 1848 he was led, through the discovery of left-hand tartaric acid, to the constitution of racemic acid. There are bottles of the right- and left-hand tartaric acids—pasteboard models of the same—"the one, if seen reflected from a mirror, being the image of the other." In 1858 M. Pasteur found that the right-hand tartaric acid in neutral media will ferment through the action of living ferments, and that these act chiefly on the right-hand acid. There is a phial of tartrate of ammonia, procured from the fermentation of racemate of ammonia, the right-hand salt being decomposed and the left remaining intact. It was supposed by M. Pasteur "that the molecular dissymmetry of organic substances might have an influence on actions of physiological and vital order," and was so stated.

There is blood drawn from a healthy rabbit into a sterilised tube, which for years has remained unaltered; also various culture liquids; single- and double-branched tube flasks. The doubly-branched tubes admit of the sterilised fluid being infected in one, while the other is kept normal for comparison. There are also a self-closing digester with manumometer for sterilising liquids; an oven for heating flasks; Schloesing's temperature regulator for water bath, which works by the dilutation of mercury; funnels for the hot filtration of viscous liquids; water-bath and regulator; funnel and water-bath; Moitessier's regulator for gas pressure; D'Arsonval's stove and thermosyphon; D'Arsonval's stove, with constant level and temperature effected by means of the D'Arsonval regulator. This is made by Weisnegg, and admits of very minute estimation of temperature—"to the $\frac{1}{10}$th of a degree." Possibly this might be useful, if modified, for gelatine emulsion making. There are other cultivating stoves.

* Dr. Thuillier unfortunately succumbed to cholera during his study of this epidemic in Egypt; Dr. Roux and Dr. Straus are now occupied at Toulon in the study of this serious malady.

Exhibited also is Pasteur's experimental brewing apparatus without the entrance of air; a gas stove for sterilising and drying vessels, and hot bath for sterilising by heat up to 120° C.; a biscuit porcelain filter for filtration in vacuo; a water filter, invented by Dr. Chamberland, for filtering through unglazed porcelain tubes at the normal water pressure. These can be readily removed, cleaned, and even rebaked for use when soiled. We must not omit the historical flasks opened by M. Pasteur at different mountain heights.

There are also various forms of apparatus which have been required for special purposes. There are beautifully-made transfusion and vaccinating instruments; the cautery of Dr. Pasquelin for bloodless operations; a modification of Dr. Roy's, and sliding microtomes; Verrick's microscopes; large and medium stands; lithographs, plain and coloured, of the silkworm moths, caterpillars, internal organs, and figures of the disease corpuscles; figures of many figured ferments found in beer and wine; also drawings of the vinegar process; while adjoining will be seen the mode of examination of silk worm moths, as carried out on a large scale, with much that is interesting in this fortunately recovered silk worm rearing, the loss of which would have proved most serious to France; and close to this exhibit is a model apparatus and drawings of the mode of Pasteurising wine by one of the large wine merchants—M. Houdart. Besides what we have enumerated, there are a few photomicrographs from negatives by Dr. Roux, which have a special claim for notice.

We had the pleasure of examining two small negatives about the size of a sixpence, which bore enlarging up to the ordinary lantern size of transparencies, and to the fidelity of these we can testify. These negatives go far to support what is not generally allowed—that better negatives of bacteria and very minute objects can be produced without the eyepiece, by obtaining more perfect small negatives, than by original large direct negatives. There is, of course, the additional trouble of copying and enlarging; but we must not let this stay our hand when we are seeking for the best work. The plan adopted by Dr. Roux, which is one to meet *rapid laboratory work*, was to fix a small camera or cell to the eye end of the microscope containing the little gelatino-bromide plate, the position of the focus and the image having been previously determined by placing a piece of plain glass in the slide, and on its *upper* surface a few scales of a moth or butterfly. These are brought into focus by a low-power objective used as a focussing-glass, and the image of the object on the stage of the microscope and the image of the scales are made to coincide. Hence, by withdrawing the little camera and inserting the focussing objective, the focus of any object on the stage can be made to occupy the exact position of the scales on the transparent glass. In other words, the focus of these and the new image are coincident, and, the surface of the small gelatino-bromide plate falling exactly on to the same plane, there can be no error through the different thickness of the glass plate, as the focus of the scales, the image of the object, and the sensitised surface are in one plane.

The illumination is by a small paraffine lamp. The arrangement is simply removal of the eyepiece, insertion of the focussing objective, and then the fixing the little camera in position. There is no reason why a somewhat larger camera may not be used, and a rather longer and larger tube adapted to the working microscope, or the camera may be in part supported, as suggested by Dr. A. C. Mercer, of Brooklyn, U.S., by a strut from the stand of the microscope. For the most perfect work it would, perhaps, be preferable that the camera should be only loosely connected with the eye end of the microscope, though otherwise a fixture. The plan of development adopted by Dr. Roux was that, we believe, recommended by Colonel Stuart Wortley, of soaking the plate in weak ammonia before applying the pyro., and then adding ammonia as required to to bring up the image. We would strongly recommend examination of these exhibits, and we must again remind those disposed to aid photographically in the study of the bacteria, that patience—the common virtue of the photographer of the infantile world—will be largely requisitioned, even under favourable circumstances.

There are other photomicrographs in the gallery of the Albert Hall; and in Dr. Cheyne's laboratory will be seen some of Dr. Koch's photomicrographs of the bacteria of disease, and a Siebert's camera; but we must not further particularise.

EXPERIMENTAL COMPARISON BETWEEN AZALINE AND EOSINE PLATES.

In order to ascertain how the different stained plates sensitised for colour represent the colours, one colour scale was photographed: I. With eosine collodion of the usual composition; II. with eosine gelatine emulsion plates (two per cent. of a 1:400 eosine solution); and, III., with azaline gelatine (one per cent. of a 1:30 solution of azaline) plates, all taken through the same yellow glass. The wet eosine collodion plate required an exposure of four minutes; the two dry plates a minute each. The result was as follows:—

Colour.	I. Eosine-collodion wet plate.	II. Eosine-gelatine dry plate.	III. Azaline dry plate.
(a) Naples yellow..	Lightest.		
(b) Chrome yellow.	A little darker than Naples yellow.		
(c) Red lead......	Black........	Black........	Grey.
(d) Dark red......	Black........	Black........	Black.
(e) Rose........	Darker than chrome yellow	Like chrome yellow	Rather darker than chrome yellow.
(f) Light green..	Like chrome yellow	Lighter than chrome yellow	Darker than chrome yellow.
(g) Dark green....	Grey	Grey	Dark grey.
(h) Cobalt........	Dark grey..	Like chrome yellow ..	Dark grey.
(i) Ultramarine ..	Black......	Like chrome yellow ..	Black.

From the above it will be seen that green acts too powerfully upon the eosine dry plates as well as upon the wet plates. A light green, which to the eye appeared darker than chrome yellow, appeared lighter than it in the photograph. Then red lead acted excellently upon the azaline plate, but quite insufficiently upon both the eosine plates. Rose colour did better with the eosine gelatine plate than with the wet eosine collodion plate. The difference between the sensitiveness of the two eosine plates for blue was very remarkable. In the wet plate it came out decidedly dark; while in the dry plate, in spite of the yellow glass, it came out *as light as chrome yellow*.

The wet eosine plate so far represented the relative values of the colours more correctly than the dry plate; but the azaline dry plate far surpasses them both—not only by its sensitiveness to yellow-red, but also by the correctness with which it reproduces the gradation between blue and green. H. W. Vogel, *Prof.*
—*Mittheilungen.*

MISCELLANEOUS SUBJECTS.

Another New Rainband Spectroscope.

A year or two ago a description was published in these pages of a pocket rainband spectroscope, made on M. Janssen's principle, by Mr. John Browning, the well-known optician, accompanied, however, by the objection that some persons were unable to see the rainband through it, and, in occasional instances, perhaps, through any other instrument. Perseverance and experience have much to do with the matter, and in some instances colour-blindness may come into play. As M. Mascart has said, one person in every ten is markedly colour-blind, usually without knowing it. In their recognition of the more delicate tints of the spectrum it is possible that no two observers are alike, and no man has the right to set up his own eyesight as that by which the eyesight of all other men should be judged. Who is to decide whether that which one man calls red has not the same influence on his brain as that which another man calls green, the colour being the same to both merely in name and position in the spectrum? Until one man can put his brain behind another man's visual apparatus, who is to answer this question?

To overcome objections as to difficulty in seeing the rainband, especially with a pocket spectroscope, Mr. Browning set to work to make one to give plenty of light and plenty of dispersion. This he did partly by the use of glass prisms specially heavily charged with oxide of lead—so heavily charged, indeed, that slabs of the glass feel almost as heavy in the hand as slabs of metal. This special glass has a faint yellowish tinge. The compound direct vision prism is placed nearer to the eyepiece than in the original instrument; in fact, it almost touches it. In the mechanical arrangements there is improvement—a half-turn of a milled head moving the telescope of the spectroscope in or out a considerable distance by means of a lever arm and pinion. Where portability is necessary, combined with efficiency, it is the best instrument of the kind I have seen. It was of constant use to me during the whole of last winter when travelling in Switzerland; and for various researches I am carrying on in connection with photography it is in constant demand. A large spectroscope is one of those instruments which are of no use to a man who does not mean to thoroughly study spectroscopy, and to go in for real hard work. For *dilettanti* use a pocket spectroscope is the proper thing, and is excessively valuable for ordinary purposes. A powerful spectroscope means hard work and hard study; it cannot, like a powerful telescope, be to any great extent made a means of intellectual recreation to all comers.

The Standards of the Photographic Society.

The Photographic Society of Great Britain having done such good work in the establishment of standard screws and stops for lenses, why should it not now do something to promote better and standard lights in developing-rooms? It might do this by fitting up a shadow actinometer of the description recently used by Professor Dewar at the Royal Institution, and testing the lanterns constructed, or in course of construction, by those who are seeking to improve the light for developing commercial gelatino-bromide plates. The test for non-actinicity might be the effect produced upon half a plate at eighteen inches from the flame of the lantern, as compared with the effect of the competing lantern upon the other half of the same plate, both halves exposed for the same time, developed in the same dish, and fixed in the same bath of thiosulphate of soda. Next, each lamp could be tested as to the intensity of its light by the shadow actinometer, by which it is possible to compare the intensities of two lights of different colours. It may, perhaps, be safely assumed that on the average the developing-rooms of photographers are twice as dark as they need be, to the unnecessary straining of the eyesight. The proposed testing would also bring out information of scientific interest; for at present very little is known about the relative space-penetrating powers of coloured lights of low intensity. When readers of memoirs bring forward new lanterns the illuminating power of each lantern should be tested by the actinometer before the reading of the paper, so that the listeners may have some idea of the value of the light brought under their notice. Knowing its illuminating power, the only remaining question will be the amount of its action upon a plate at a fixed distance from its flame—say eighteen inches or two feet.

If the Photographic Society had standards for testing varieties of apparatus, so as to be able to do for photography that which Kew Observatory does for meteorology, its attractiveness and usefulness would be greatly increased. It should be able to test lenses, lanterns, and plates by means of standard apparatus, and give certificates of the result in figures—for a small charge, if need be—as at Kew. Most scientific societies have an excellent library for the use of members. Why is the Photographic Society without one?

The standard light used in the actinometer might be that of the Carcel lamp, with its light passed through a given thickness of solution of pure bichromate of potash in distilled water; or the standard candle used for the testing of the illuminating power of gas might be employed. In some cases the lights from two competing lamps might be directly tested against each other, instead of employing a standard light. Standards of measurement in the rooms of the Photographic Society would abolish a certain amount of vague talk, and give a distinct impulse to the progress of photography. It is to be hoped that at the forthcoming Congress on International Photographic Standards at Brussels, no attempt will be made to found an international establishment with photographic standards, but that each nation will have one of its own. These suggestions are made on the supposition that the Congress does not meet merely for the vulgar but useful commercial purpose of establishing uniform sizes for photographic plates, but that it will have some scientific ends in view. When does the Congress meet?

Studios with Top Light.

On the high road from England to Switzerland by the quickest route *viâ* Calais, Boulogne, Rheims, and Chalons-sur-Marne—a cross-country track with but one through train in the twenty-four hours—the traveller, after speeding in darkness through central France, in the cold grey of morning finds himself near its eastern borders between the Vosges and the Jura mountains, both too far off to impart much in the way of beauty to the scencery, and Belfort is usually the first town of any size to greet his vision. Nobody who is anybody ever gets out at Belfort, where everybody would be glad to see somebody, who, however, alighteth not. Why should he? and is not Basle close at hand? However, some two or three months ago I had the curiosity to visit this same Belfort. It is a military town, hot and dusty, very strongly fortified, and the scene of fierce fighting during the Franco-Prussian war. Near the theatre is a photographic establishment, perhaps the largest in the town, and the studio is built on the ground, with its glass side close to the street, just where the face of the side wall of a house or garden would be. Small boys and others are prevented from contemplating the features and disturbiog the peace of mind of the sitters by the use of ground glass instead of plain glass for the side of the studio, and this glass is protected from injury by wirework. As the side street is narrow, and has houses on the other side, the studio has too much top light. The ground glass would have obviated this to some extent by catching some of the light from the sky and throwing it into the room; but the owner has made the grave error of placing the polished side of the glass outwards, so that its shining surface reflects much of the needed light outwards and downwards. The example is, therefore, published here as a warning to others. In spite of all disadvantages the artist, nevertheless, turns out very good pictures. Scientific knowledge is but the servant of art-taste in a good photographer, and a man with good art-taste, without techical ability, will often produce a pleasing picture where the scientific mechanic fails. The natural elegance and good taste of the French tell greatly in their favour in photography.

Near the establishment of this Belfort photographer is that of a chemist, and photographic chemists are so honest in France they let you know what to expect; for this one has a plate of brass three or four yards long inside his window, with the word "Roguerie" printed on it in large black letters. "D," the actual first letter of the word is hidden from view because the brass plate is too long for the window.

The Dáphnia Pulex.

In his lecture at the Royal Institution Professor Mascart exhibited an experiment with a great number of specimens of the *Dáphnia Pulex*, or common water-flea. These were swimming about in water contained in a vessel with flat sides. The rays of the spectrum were sent through the bottle, upon which the largest and presumably the most sober-minded of the fleas took up their positions in the green rays, so as to form a living band in that part of the spectrum. That interesting crustacean, the *Dáphnia Pulex* of Latrielle and Larmarck, delights to abide in horse ponds, and where the water is green and juicy, though it is found also in running streams. Its moral propensities are of a low order, since it passes its whole life with a single eye to its own interests; in fact it has but one eye, and that a big one, connected by nerves with the two lobes of its brain. I question whether Professor Mascart was right when he suggested that the larger water-fleas selected green light because they were colour-blind. However honourable their position of being in his bottle and before the Royal Institution, perhaps they were home-sick, and careered about in the green ray merely in the hope of finding an outlet to their green pond with its flea umbrellas of green duckweed. That the smaller ones did not do the same merely proves that they were gay young things who appreciated the grandeur of their position. They belong to the *Cladócera*, or "branch horns." They have five pairs of feet, and two pairs of antennæ, the lower pair very large and used in swimming; the feet are "not much," and within the shell. Their motions are lively and brisk. In Professor Mascart's bottle they betrayed no lack of energy and excitement. In their native ponds and ditches, where no doubt they will be much sought hereafter by photographers who wish to use them to indicate the new flea line in the spectrum, they sometimes travel in a band a foot wide and several yards long, with no doubt leaders in front like certain birds of passage. They are frightened at shadows; for let but a new shadow fall upon the water the whole army of fleas vanishes in all directions. They flee away, so to speak. The beating of their hearts is rapid and isochronous. Phrenologists say that the brain at the back of the head denotes animal propensities; the whole of their brain is at the back of the head; they have no brain in front for the development of the intellectual and moral faculties. They carry their eggs on their backs, underneath their shells, and hatch them there. The young are unlike their parents—have no shell, no abdomen, and but few limbs. The egg-carrying part of the body is opaque at certain seasons of the year. They are three or four times as large as the land flea, to which they are related only in name. Their countenances are rigid, and betray little emotion under all the changing vicissitudes of life.

W. H. Harrison.

ON STAINED GELATINE PLATES.

The dye prepared by me, and which I mentioned at the conclusion of my last article, and which I have decided to call "azaline," has, on further trial, turned out a very excellent *optical sensitiser for gelatine plates*, though its action upon collodion is less excellent. It has three lines of absorption, two of which lie in the yellow-green and one in orange; and corresponding to the latter it produces quite a considerable sensitiveness to red, but has a slighter sensitiveness to green than eosine. This, however, is no disadvantage; rather it is an advantage, for green acts too powerfully upon common eosine. It is, however, very surprising that azaline does not, like eosine, diminish the collective sensitiveness to white light, but rather *increases* it, and with some emulsions even doubles it. For this reason I succeeded in taking a photograph with it of an oil painting with figures in white dresses without the slightest solarisation of the whites. The exposure required for a life-sized oil painting taken through dark yellow glass in bright weather was only a couple of minutes. The experiments will be continued.

H. W. Vogel, *Prof.*

—*Mittheilungen.*

ON THINGS IN GENERAL.

"Messrs. G. West and Sons have a frame of studies of yachts elaborately retouched;" so say the Committee of the Cornwall Polytechnic Society in their report upon the exhibits. Some value has been attached at one time or another to the awards of this Society to photographic pictures; but when this second time the Committee go out of their way to libel a photographer who has produced some of the most exquisite gems of pure photography that ever adorned the walls at Pall Mall, and call his examples of pure photography "elaborately retouched," the value of their verdict will be considered as about equal to its want of truthfulness. Messrs. West and Sons have just cause for grave complaint. Another gentleman they take under their wing in a very kind manner:—"The Judges are pleased to note the marked improvement in his exhibits over last year." What a glow of satisfaction would suffuse the cheeks of that gentleman at this kind expression of pleasure at the improvement he is making. It would almost annul the feeling of horror at the want of grammar in the language adopted to express their gratification. This report is very good reading. Of one set of pictures it says:—"They are a little too black and cold, and in many instances the subject is too low in the plate, which dwarfs the hills." Here is a nice little puzzle for the wet days, to discover whether the subject or the plate dwarfs the hills. "The Judges are of opinion that this gentleman can do better work, and hope he will profit by these remarks!"

I was interested to note the discussion at the Parent Society last month about quick exposures. Several members expressed the opinion that the quickest of exposures did not necessarily produce a more correct or artistic representation of the object than an exposure really quick but relatively slow. This is a text I am to get prosy on, I do believe, but its importance must be my excuse. To me the representation of quickly-moving objects by a picture depicting just one phase of the motion is an outrageous absurdity. Mr. Muybridge's photographs were invaluable, but to the anatomist only—not to the artist. Some of the positions of quickly - travelling animals were actually ludicrous; no artist would attempt to paint them in a picture. Similarly with sea pictures—or, perhaps, I should say, wave pictures—as discussed at the above Society. Everyone knows that an extremely-quick exposure would give the reflected sheen of the sun on the water as a series of reflections of individual distorted suns, and not as that long line of light which the eye perceives, or, rather, records, upon the brain. And so in breaking waves and rolling surf. Where the motion is comparatively slow instantaneous pictures are admirable, but where changes follow in rapid succession the eye only tells the brain of an average of a number of different pictures placed on one another—an average taken after Mr. Galton's principle. Mr. G. W. Wilson, in his Scotch views, when he produced his most beautiful photographs of rolling waves years ago, only used his cap to cover and uncover his lens with, and artistic indeed were his results. I do not wish to be understood from what I write that I object to quick exposures altogether; far from it. Some most exquisite pictures have been so taken; but the subject should be suited to the process, and not the process to all subjects.

Whenever Mr. J. R. Sawyer gives us a paper it is sure to be practical and to contain valuable hints. Such was his last on *Commercial Fabrics Suitable for Dark-room Illumination.* But what did he mean by putting the task of contracting the pupil of the eye upon the ciliary muscles which really work the lens of the eye? The muscular fibres of the iris are not the ciliary muscles, as his words would indicate; and so far from those muscular fibres acting slowly they form a conspicuous example to the contrary, for they act with great rapidity, though other unstriped muscular fibres do act slowly.

I note that in the discussion upon Professor Vogel's discovery, at the meeting of the Berlin Association for the Cultivation of Photography, two photographic reproductions of a chromo-lithograph were shown—one done in the usual way, and the other by his stained collodion process. In comparing the two copies it was noticed that the grain of the paper showed very much more clearly in the picture done by the ordinary process than in that by the stained film, and the reason given was that the shadows cast by the inequalities of the paper of the original were caused by reflected light and were yellowish in tone—a tint to which ordinary collodion is very sensitive, but the stained collodion very much less so; hence these shadows are not strongly reproduced in the latter. This is all nonsense as at present written, and it appears to me that the simple explanation is that the picture showing the grain most closely was under-exposed. Anyone accustomed to copying pictures upon paper knows that such is the usual effect of under-exposure.

Apropos of the subject of compressed oxygen that has been so much discussed of late, I was much amused by the perusal of your American correspondent's remarks upon the subject. "In England," he says "(where strength is universally sacrificed to weight), a small garden roller called a 'bottle' has," &c. That is very neat; "garden roller" is a very good term by which to describe these vessels. It is a pity that the system of compressed gas is not more general; I expect, however, that it will be ultimately. There seems to be some difficulty anticipated as to the heat produced in gas compression, it might be equally useful to give a word of warning as to gas expansion. A compressed gas-holder, if allowed to give out some considerable portion of its contents at a quick rate, would become so cold as to be almost dangerous to handle.

According to a report of the discussion at the Photographic Society of Great Britain, on the 24th June, one of the questions put forth at the City Guilds examination was—"What is the cause of green fog?" I could very readily understand the question being put as to *a* cause; but to assume, as must have been done if the question were properly reported, that there was only one particular cause is to assume what most assuredly has never been proved, and so the question was a misleading one.

To sum up photographic optics in a few dozen lines, and to describe the principle of achromatisation in a few dozen more, might seem an impossible task; yet Professor Rucker, in his lecture to the Leeds Photographic Society, almost succeeded in doing this, and gave a compact and useful lecture upon this important subject, about which, strange to say, there is more ignorance than upon any other in connection with the art among the general body of photographers.

I observe in *Recent Patents* one for preparing prints for colouring after a plan somewhat suggestive of crystoleum processes. I do hope we are not going to have another crystoleum fever. A year ago nearly every young lady in the kingdom was learning the art and producing more or less (to herself) satisfactory pictures in all the colours of the rainbow. The "craze," I am glad to say, appears to have almost died out. I have a strong idea that many ladies "went in" for crystoleum painting with the idea that by paying a guinea or two for lessons she had learnt a profession which would give her quite a settled annual income. How many have there not been doomed to utter disappointment! People never will believe that the smallest and lightest handicrafts cannot be learned without practice. Far less likely is it that the power to do artistic work can be picked up in a few weeks' time.

FREE LANCE.

FOREIGN NOTES AND NEWS.

DR. LOHSE ON ISOCHROMATIC GELATINE PLATES.—OBSERVATIONS ON THE SAME BY HERR SCHUMANN AND HERR OBERNETTER.—HERR ALBERT'S CLAIM.

IN the *Archiv* Dr. O. Lohse, of Potsdam, gives an account of how he prepared eight solutions of different strengths of eosine, the weakest containing but 0·0005 of a gramme of eosine to 100 c.c. of fluid, a proportion of 1 : 200,000, in which the dissolved eosine was, of course, quite imperceptible to the naked eye, yet he found that bromide of silver films saturated with it were rendered perceptibly more sensitive to yellow. This confirms Professor Vogel's experiments. A little ammonia was added to the preparatory solution of eosine and no special emulsion was used, only some ready-made plates were placed in a bath containing the solutions of different strengths.

In a subsequent article Dr. Lohse recommends for the same purpose, as a substitute for eosine in the preparation of isochromatic plates, an alcoholic solution of turmeric root. He found that this extract did better even than eosine, because it acted also upon the red part of the spectrum and increased the sensitiveness of that part where there was a minimum action with eosine. The sensitiveness to colour between the Fraunhofer lines D and H—that is, from yellow to violet—is nearly equal, being without any great preponderance of action in the yellow as compared to blue, such as occurs in the case of eosine. Dr. Lohse is of opinion that a mixture of eosine and tincture of turmeric may be used with advantage for staining plates. Dr. Lohse's experimental plates were prepared, like his eosine plates, by placing ordinary gelatine plates in a bath of ten c.c. of water, ten c.c. of ammonia (density not given), and a small quantity of alcoholic extract of turmeric. The eosine series was prepared by dissolving in every 100 c.c. of water containing ten per cent. strong ammonia, the following quantities of ammonia:—No. I., 0·5 of a gramme; No. II., 0·25 of a gramme; No. III., 0·125 of a gramme; No. IV., 0·0625 of a gramme; No. V., 0·0313 of a gramme; No. VI., 0·0078 of a gramme; No. VII., 0·0019 of a gramme; and No. VIII., as already mentioned, 0·0005 of a gramme.

In the *Wochenblatt* Herr Schumann says he has tried the extract of turmeric as recommended by Dr. Lohse, but got no favourable results with it. Herr Obernetter, who has also been experimenting with turmeric, writes that the sensitiveness to red induced by it is too slight. Elsewhere [see page 473] Dr. Vogel recommends a new dye, which he calls "azaline," and which he thinks superior to eosine on account of its action on the red rays.

A certain Dr. Albert claims to have used stained plates for two years, and scouts the idea of photographing through yellow glass. The negatives he has sent along with coloured originals to the *Archiv* seem to bear out his assertion; but he gives no details as to what substances he has employed in order to get a truthful reproduction of the colours.

Our Editorial Table.

AMATEUR PHOTOGRAPHY. By D. J. TAPLEY.
New York: S. W. GREEN'S SON.

WE hear a great deal about the rapid spread of amateur photography in America since the introduction of gelatine plates; but, if American amateurs are satisfied with the intellectual food provided by the author of this work, we fear they will do little credit to photography. We do American amateurs the justice of believing, however, that, as a body, they are a little more advanced in intelligence than their would-be instructor would seem to think.

The motto on the title-page of the book is "Easy as rolling off a log." We do not quarrel with the author in adopting this motto, as we presume he alludes to the attainment of his own standard of efficiency, speaking of which he says:—

"After a few months of practice with no instructor except a book furnished with a cheap outfit, I have succeeded in making pictures that are a source of satisfaction to myself and friends, and that I am willing to compare with those of the average professional."

And then he straightway commences to write a book of instruction!

Of himself the author is good enough to inform the reader that he was "just forty-nine on the 22nd of last February," and then follow several pages of "twaddle" which, though they serve the purpose of filling up, have no earthly bearing on photographic instruction. After this he plunges *in medias res*, and the reader is indulged in a dissertation on photography, containing about as much information as would be extracted by an intelligent eight-year-old schoolboy from a one-hour's discourse by a lecturer who had never seen a dry plate in his life. The developing instructions, for instance, are specially good, and occupy eight lines of large type. They are as follow:—

"The plate is again covered from the light and brought to the 'dark room' (we use the bath room, as we can get plenty of water and can easily shut out the light), where, by the light of a red lantern, it is taken out of the plate holder and treated to a simple chemical bath which changes what was apparently a plain glass plate, covered with a whitish substance, into a beautiful picture."

Verily it is so simple that the novice must think it even easier and certainly far pleasanter than "rolling off a log!"

In connection with printing, the author sagely remarks that "the object of toning is to clear up the picture, making the whites white and the blacks of the particular dark shade that pleases the artist." Also that "the purpose of 'fixing' is to neutralise the chemicals that are alterable by light and make the picture permanent." In this chapter on printing, however, Mr. Tapley proves that his "few months' practice" have taught him one thing; for, speaking of printing, he says—"and in fact you may study this branch for years and still find something to learn." We may add—"practice is better than precept."

But we need go no further in showing how the pages are filled without affording a glimmer of information that a learner could find of any use. But we may conclude with a remarkable instance of how the "learner" may be led astray. Under the head of "Actinometer Tests" we have the following precious statement:—

"The 'actinometer' is a hydrometer for testing density of fluids, having a scale which indicates the number of grains to the fluid ounce. Thus a solution of 50 grains of nitrate of silver to the ounce of water allows the actinometer to sink to the figure 50, and the solution is said to be 'fifty grains strong.'"

In this attempt at authorship Mr. Tapley has no doubt succeeded *to his own satisfaction;* but then he has shown himself to be very easily satisfied. We have devoted so much space to the matter as a protest against the combination of ignorance and effrontery that induces a man after "a few months' practice" to set himself up as a teacher of his fellows. If the book be utterly worthless as an instructor we can, at least, recommend it to our numerous American subscribers as affording for its size a very large amount of comic reading, and, being well got up and profusely illustrated, the first edition may go off successfully. By that time, perhaps, Mr. Tapley will have begun to learn that neither photography nor book writing is quite so "easy as rolling off a log."

Meetings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

AT the technical meeting of this Society, held on Tuesday, the 22nd inst., the chair was occupied by Mr. J. Spiller, F.C.S.

In the course of some observations upon the necessity of having correct reports of the transactions of the Society, the Chairman remarked that a curious instance of inaccurate reporting had recently occurred in an account contained in a technical scientific journal, where Professor Macleod had been described as having exhibited an apparatus for automatic registration of sunshine by means of a water lens, the fact being that no apparatus had been exhibited, and the lens which was described was an ordinary glass one, and not a globe of water, which would be unsuitable from its liability to burst with frost.

Mr. ANNAN (of the firm of T. and R. Annan, of Glasgow), on the invitation of the Chairman, exhibited a series of examples of the photo-engraving process (Klic's), as carried out by that firm. The prints were of a very varied character, including copies of paintings, engravings, landscapes, interiors, and portraits. Amongst the latter were some striking examples. One of the Duke of Buccleugh strongly recalled the fine prints on salted paper produced twenty-five years ago by Messrs. Hennah and Kent.

Mr. W. M. ASHMAN showed four negatives taken on plates of the same batch and similarly exposed, but developed by different methods. No. 1 was developed with pyro., sulphurous acid, and alkali, on the plan recommended by Mr. Monro in the April number of the *Photographic Times*. No. 2 was developed with the usual quantities of pyro., ammonia, and bromide. No. 3 was like No. 1, but with ammonia substituted for the alkali recommended. No. 4 was with Newton's latest formula containing formic acid. He (Mr. Ashman) thought that No. 1 gave the best result, and then No. 4. No. 3 he considered to be ten times over-exposed. As to the time occupied in developing: No. 1 had taken two minutes and No. 4 ten minutes.

Mr. W. E. DEBENHAM inquired whether he was to understand that the use of No. 3 developer would allow an image to be brought out with one-tenth the exposure required by the others.

Mr. ASHMAN said scarcely that, but that it was a mixture which required a restrainer, and did not work properly without it.

Mr. T. SEBASTIAN DAVIS thought that the image produced by No. 2, the ordinary developer, was the best. He found that be got the best results in developing from using twice as much bromide as pyro.; but in hot weather, such as that experienced recently, he considered four times as much bromide as pyro. better still.

Mr. ASHMAN inquired whether any other member had had any experience with formic acid in the developer.

Mr. T. BOLAS observed that with the small quantity used by Mr. Newton the effect was probably inappreciable.

The CHAIRMAN asked Mr. Ashman to give the formula in full.

Mr. ASHMAN did so. [It will be found in our issue of the 11th inst., in the report of a meeting of the London and Provincial Photographic Association.]

Mr. DAVIS said that M. Audra had recently recommended the use of a two-per-cent. solution of water-glass for a substratum for gelatine negatives, as a preventive of frilling, and as causing the emulsion to flow freely on the surface. He intended experimenting with it himself, and would report results at the next meeting.

Mr. A. COWAN knew of one commercial plate-maker who prepared his plates in that manner, and used no chrome alum in the emulsion. It was, therefore, probably efficacious in preventing frilling.

A question was read:—"What is the use and value of the addition of alkaline citrates to the developer?"

Mr. DEBENHAM remarked that when the use of citrate in the developer was introduced by Mr. G. Watmough Webster it was in order to overcome over-exposure. It seemed, therefore, probable that when it was employed a longer exposure was necessary.

Mr. COWAN had found that a plate exposed six times too much came up with citrate undistinguishable from one that had received the correct exposure.

Mr. F. W. DONKIN had found a similar effect with ten times the proper exposure.

It was arranged that the discussion of this question should be adjourned till the next meeting, and the Chairman expressed a hope that members would experiment in the meantime and report thereon.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION

AT the meeting of this Society, held on the 17th instant, the chair was occupied by Mr. A. Cowan.

Mr. J. H. HARE, on behalf of Messrs. J. and H. Dale and Co., showed a studio clock having a large seconds hand which, in the ordinary way, was out of gear, and did not move with the other hand, but stood at zero. By means of a Leclanche battery the clock was in electrical connection with one of Cowan's double drop-shutters. When the exposure was commenced by the fall of the first dropping piece, the seconds hand was thrown into gear and continued to move until the exposure was terminated by the fall of the second dropping piece, which closed the lens. This movement threw the hand out of gear again, and it returned to zero in readiness for the next exposure.

Mr. W. AYRES passed round some prints from negatives taken on gelatine plates during a recent professional tour through Scotland. The subjects were of the most varied character, including landscapes, interiors, and boats in motion, &c. Mr. Ayres also showed a tool made for cutting circles out of ebonite.

Mr. W. M. ASHMAN showed two pairs of prints made in April last. One of each had been kept covered up in envelopes; the others had been exposed in show cases. The latter, although not exactly faded, had changed in tone, becoming decidedly redder. This was attributed to the joint action of the light and exposure to atmospheric influences.

Mr. W. K. BURTON thought that so far the change was an improvement.

Other members spoke of having noticed a rapid change in prints that had been exposed in certain positions, such as railway stations, where damp had had access to them.

A question was asked as to whether particulars had been received of the method of producing gelatino-chloride opals employed in obtaining the one shown at the previous meeting.

The SECRETARY replied that they had not.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE members of this Society enjoyed an excursion in Shropshire last week, under the guidance of their Hon. Secretary, the Rev. H. J. Palmer.

Starting in carriages from Shrewsbury, the first stage of the journey ended at Condover. Here the centres of attraction were the church, the splendid Elizabethan mansion of Colonel Kennard, and Condover House—an extremely beautiful black and white building of the 13th century. Miss Carr very kindly showed the beauties and curiosities of the interior to the visitors, and large numbers of negatives were taken here and at the hall.

A drive of a few miles to Pitchford followed, and, with the permission of Colonel Cotes, very fine pictures were obtained of the old hall and church.

The next halting-place of the party was Acton Burnell, where there is a fine ruin of a building in which Edward I. held a parliament in 1283; but no negatives were taken, owing to the necessity of pushing on to Wenlock.

The drive over Wenlock edge, and the magnificent panorama from the ridge, were greatly enjoyed. But the culminating pleasure of the day was found in the ruins of Wenlock Abbey. These abound in artistic "bits," and the abbot's house, occupied by Mr. Gaskell, M.P., supplied as fine a subject of this class as could be found.

About a hundred negatives were taken during the day, and the only things to mar the enjoyment of the excursion were the necessarily short stays at each spot, and, last but not least, the difficulty of finding trains and places for Birkenhead in the terribly-congested state of the traffic at Shrewsbury. But, in spite of all the drawbacks of the day, it was considered to have been the pleasantest and most profitable, from a photographic point of view, of this season's excursions of the Association.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

THE third of the current year's series of outdoor meetings of this Society was held on Saturday afternoon last, the 19th inst., at Dilston, near Corbridge-on-Tyne. The ruined Hall at this romantic spot was formerly one of the residences of the ill-fated Earl of Derwentwater, and it, together with its surrounding picturesque scenery, has oftentimes formed a happy subject for artists of all kinds—the wielders of pen, pencil, brush, and photographic lens alike.

Mr. E. Goold, of Elswick Lodge, Newcastle, was the leader of the expedition, and under a propitious sun and sky a fair number of plates were exposed, and have since turned out satisfactorily. Mr. J. P. Gibson, of Hexham, with characteristic hospitality, entertained the members to a substantial tea, and afterwards showed them through his large studio of photographic views, which for variety and good workmanship are equally admirable. Altogether the gathering was most agreeable.

The next outdoor meeting will be held at Bywell, on Wednesday, the 6th August, under the leadership of Mr. E. Dodds, Low Fell, Gateshead.

ST. HELENS ASSOCIATION FOR THE PURSUIT OF SCIENCE, LITERATURE, AND ART.

PHOTOGRAPHIC SECTION.

A MEETING of this Section was held on Wednesday, the 25th ult.,—Mr. Heather in the chair.

Mr. BROOK exhibited his new $8\frac{1}{2} \times 6\frac{1}{2}$ camera, by W. Watson and Sons, London, with Ross's symmetrical lens, which was very much admired.

Mr. LEES presented the Section with an illuminated copy of the rules. A cordial vote of thanks was accorded to Mr. Lees for his presentation.

Mr. BROOK showed about a dozen negatives of views taken at Lymm. Three of these, which should have been the best, were fogged. An inquisitive young lady at the above place opened the slides to see the pictures whilst Mr. Brook was in the next room. He (Mr. Brook) will lock the bag in future. The rest were very good, including two negatives of three St. Helens celebrities, namely, the most corpulent men in town, whose total weight was 980 pounds.

The CHAIRMAN described some experiments he had been making with boiled and cold emulsion-making. He was not very successful with the cold, and was now more than ever a disciple of the boiling process.

After the inspection of a number of prints and chemical photographs (not by Mr. Sherlock's new process) the meeting was adjourned.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

THIS Society met on the 6th June,—Professor H. W. Vogel in the chair.

Dr. Liesegang forwarded a copy of his work *On Silver Printing and Enlarging, and the Collodion Process.*

The Chairman then read a circular received from the Northampton Museum authorities regarding the prospective International Photographic Exhibition, to be held there from the middle of December.

An unusually good photograph by electric light, by Herr Kurtz, of New York, was shown and favourably commented upon.

Herr QUIDDE inquired whether most light was lost through diffusion by Herr Kurtz's system of electric lighting, or by absorption by the paper reflector through Mr. Vanderweyde's system.

The CHAIRMAN replied that he thought Herr Kurtz's system was the better of the two; but that was merely his impression, as he had no exact data to go by.

Herr JOOP suggested replacing the tissue paper or ground glass which covers the aperture of the lantern directed towards the sitter by ribbed glass, which would absorb less light.

The CHAIRMAN showed some lichtdrucks of photographs, by his new process, of the colour scale, and then spoke of his endeavours to render gelatine plates sensitive to yellow, &c. He had prepared a new dye which, in consequence of its resemblance to the bloom of azaleas, he called "azalin." It had a very good effect upon gelatine plates and upon dry collodion; but, on the other hand, it was not very useable with wet collodion. Herr Obernetter had already tried it upon his emulsion, and had sent him (the Chairman) two sample plates stained with it. The plates were shown and were copies of oil paintings, which showed in the most striking manner the action of Professor Vogel's dye. Herr Obernetter wrote that he had also tried these stained plates when taking landscapes, and had secured surprising results. The superiority of the azalin plates was most striking in the case of red and also of green, the latter acting too powerfully upon cosine. Two sample negatives of the colour scale, taken upon a plate stained with eosine and with azalin, showed this strikingly.

Herr SCHULTZ-HENCKE showed a gelatine plate intensified with Herr Anders' blue intensifier. The intensification proceeded very smoothly, but he could not tell them what the formula was, as Herr Anders had applied for a patent, which had not yet been granted; but it was identical in principle with Dr. Eder's blue intensifier for collodion plates, so that the validity of a patent for it might be questioned.

Herr Roloff read a small pamphlet written by him and intended for the general public—*What One Should Do at the Photographer's.* It is intended for distribution, and contains hints as to the choice of a suitable costume, &c.

This concluded the business, and the meeting was adjourned.

Correspondence.

THE ETHOXO-LIME LIGHT.

To the EDITORS.

GENTLEMEN,—So far from the ether-oxygen lime light having been "popular" here at the time I applied for a patent in connection therewith, I believe it was not used by anyone in this country. I had never heard of it, and believed that I was the first to pass oxygen through any kind of chamber containing ether and connected with a blow-pipe.

The claims in my original application for a patent covered all this, and when I discovered my mistake (while looking over a file of THE BRITISH JOURNAL OF PHOTOGRAPHY at the Franklin Institute), I wrote to the patent office examiners, calling their attention to the publication, and amending my specification and claims to cover only what was unquestionably my own.

Anyone who visits the U.S. Patent Office may examine the record of proceedings in the case, and see that I did this before the examiners had taken any action on my application, and that they then allowed the patent without making a single objection to my claims. Even now, I have not heard of anybody in this country who uses the ether-oxygen light with any other than my patented apparatus. One who tried to use the "wash-bottle generator" had an explosion which frightened him so badly that he was afraid to try even my apparatus for some time; but he now uses it and praises it.

In view of these facts, I think you will agree with me it would be unkind to make it appear that I tried to secure for myself any credit which was justly due to the English inventor.—I am, yours, &c.,

702, *Chestnut-street, Philadelphia, U.S.A., July 11, 1884.* FRED. E. IVES.

ROYAL CORNWALL POLYTECHNIC SOCIETY'S EXHIBITION.

To the EDITORS.

GENTLEMEN,—Allow me to remind intending exhibitors at the above exhibition that pictures for exhibition must not arrive later than August 5th, at the Polytechnic Hall, Falmouth.

I shall be most happy to supply prospectuses and forms of entry, which must be filled up at once.—I am, yours, &c., WM. BROOKS.

Laurel Villa, Wray Park, Reigate, July 22, 1884.

OXYHYDROGEN EXPLOSIONS.

To the EDITORS.

GENTLEMEN,—Referring to Mr. Lewis Wright's observations, under the above heading, in last week's issue: he asks for a case in which an explosion has taken place through dust in the bag. I take the liberty of stating an incident which happened a short time back to a Mr. Dallen (whom I have not asked if he has any objection to my mentioning his name, but have no doubt for the information of those interested in the matter he has not).

The accident was peculiar. Shortly after commencing his lecture (say about ten minutes, more or less) he perceived the oxygen bag in flames, but nothing whatever to indicate the cause. Mr. Dallen asked me if I could tell him the cause, but I could only surmise the following:—The bag, when being placed between the pressure-boards, was shaken, so that the particles of dust or canvas were heaped, so to speak, before the tap. This dust would float or be blown up to the nipple, and there get lighted, the oxygen supporting its combustion. These particles of dust may be conceived (with the help of the oxygen) to have ignited each other, and thereby, as a train of gunpowder, carry the light from the jet to the bag, firing the latter (causing no explosion, there being insufficient dust floating), until the oxygen was consumed.

The pumice, or tin safety-chamber, if used in this case, would have screened the dust, and hence have saved the bag.—I am, yours, &c.,

33, Balaclava-road, Bermondsey, July, 21, 1884. R. R. BEARD.

THE PHOTOGRAPHIC SOCIETY: ITS REPORTS AND THE PHOTOGRAPHIC PRESS.

To the EDITORS.

GENTLEMEN,—I must once again beg to trespass upon the Editors' space in reference to this matter; and I also ask that they will not cut out any portion of *this* letter—the last* with which I shall probably trouble them for some time.

First, as regards the Editors' remarks. If at any time a statement should be published that the Editors think or wrote that which they did not think or write, should they expostulate and explain we shall all know that they are "airing" their "little grievances;" and we shall have been taught how to pity, no less than to despise, their weakness in so doing. But, of course, the Editors are above so great a display of weakness; they are above implications, and above caring for what any may think of them. They are above caring even for their own ideas. Large-minded Editors! If the Editors had not only referred to my original letter, published in the *Journal* of the Parent Society, but had also looked up what they had written in an article upon it, they might have seen in what the "misrepresentation" consisted.

Before I proceed let me, in answer to the Editors and Mr. W. E. Debenham, dispose of this word "misrepresentation." Mark, I have accused none of *wilfully* misrepresenting me. I wrote "misrepresented, or misread." Now, misrepresentation might be due either to misreading, to forgetfulness or inattention to what had been read, or to wilful misstatement. The latter, of course, would be highly culpable and dishonourable; the others are comparatively venial sins. If a man writes that which *is not the case*, does he not "*misrepresent*"—not wilfully it may be? However, I do not wish to discuss the precise meaning of the word, though I hold that my view is correct; and I shall not quarrel with any should they take a different view, but shall content myself by simply stating that I inferred no *wilful* "misrepresentation."

To return to the Editors, who cannot discover "the slightest ground for the charge *(sic)* of misrepresentation." The Editors, in their leading article (June 13th), unquestionably make it *appear* that I object to "condensation of a speaker's remarks while still retaining his sense," whereas I really object to *incorrect statements* and to *total omissions* of matter. My exact words are "errors and omissions."† If the Editors will quote verbally any portion of my letter they will fail to make it appear that I meant what they state or insinuate I meant. I lay no value on a general and loose statement; neither do I consider that those who "trail red herrings across the scent," as some of the writers do, are worthy of much attention. What do my readers think? Is it not most convincing and fairest to face *each statement* boldly, fairly, and squarely, burking nothing, avoiding nothing, and thinking nothing that has been put forward unworthy of comment? Do not my readers agree that the high-handed, "superior-to-that-kind-of-thing," style is but a poor substitute for solid argument?

Why I should ever have been represented as making an attack upon the "weekly periodicals" (it seems to me that this view has been taken) I am at a loss to conceive. In times past I have done my share in supporting the weekly periodicals—especially this Journal—with my pen; and I have been told that my contributions were valued, but, perhaps, this was "all humbug." I have received no remuneration; have accepted no remuneration when offered; and have, as events have shown, received but little credit or acknowledgment—at least from most quarters. I am sure my conduct towards the "weekly periodicals" has shown me anything but a detractor and attacker of them. I only value *truth*—more especially when the "truth" applies to *myself;* and in this I hope I shall not be blamed. I would have the reports of the Society correct, and I would have the photographic periodicals also correct. What sin is there in this? And what harm is there in pointing out how one honestly believes the end might be attained? One writer (I do not wonder he is ashamed of his name appearing) insinuates—or am I "misrepresenting" him?—that my "photographic ideas do not soar any higher than bartering or exchanging." What a mean "red herring" that sentence is! Of course it was apparent to any one than by "bartering" an *exchange of ideas* was meant. Was it likely that I could have intended to say that any of the members communed thus:—"If you will tell me how to do so and so, I will in return give you my method," &c.? Certainly not. "Ideas," whether "luminous" or otherwise, do not, however, generally emanate from one individual only at any photographic meeting; and sooner or later all members become givers and receivers to a greater or less degree. How eloquent in encouragement are these words of the anonymous gentleman to those who, knowing what I have freely given, intend to follow in my steps, or, indeed, to surpass me, which, of course, many may readily do! Now I may be wrong, and there may be generous spirits who are above so sordid (?) motives; but I am strongly of opinion, the said anonymous writer notwithstanding, that the great bulk of members attending meetings of societies do so quite as much with the object of learning as with the object of imparting knowledge to others. These value the meetings on account of the *interchange* of information. Though it is more gratifying or "blessed to give than to receive," still a little of both giving and receiving is generally conceded to be most beneficial. But I am sure some readers will blame me for wasting words upon so good a specimen of combined hair-splitter and herring-trailer.

I turn with greater pleasure to Mr. A. Pringle's letter. I am sure I did not intend to convey any such meaning as that Mr. Pringle played the twofold part—"paying his guinea with one hand and decrying the Society with the other." I did not refer to him. Were there not sufficient writers to whom I might allude without his finding the necessity for attaching my words to himself? On the contrary, I consider Mr. Pringle an honest and straightforward writer, who, like myself, when he thinks in a certain way and opportunity offers, states his ideas boldly and with courtesy. If Mr. Pringle differs from me, by all means let him—and others also; I am sure I shall have no complaint against him. I have no wish to thrust my ideas down people's throats; neither has Mr. Pringle. We only desire that each writer, who writes courteously, may receive courteous treatment and fair and open criticism. But Mr. Pringle will concede that I must defend myself; and when he "misrepresented," "misstated"—or what you will—my words, was it not most natural and proper that I should make the statement respecting his letter I did? Whatever may not have been plain in my original letter I have made plain since; and I do not understand why a simple suggestion, honestly and courteously expressed, should have raised so polemical a spirit in the Editors and in certain of their correspondents—more especially the latter; for the former have a certain literary *amour propre*, which is only natural after all. But I do think that the Editors might have discussed, or let alone, my proposal in a rather more amicable spirit.

As to Mr. W. E. Debenham: he is even more incorrigible than Mr. Pringle. I believe Mr. Debenham really *likes* someone to "tread on the tail of his coat." But no; I did not include Mr. Debenham among "the other writers." I did not write "all the other writers;" but I acknowledge it would have been better to have written "like most of the other writers." However, I may state also to Mr. Debenham that there are two kinds of "misrepresentation"—inadvertent and wilful. As we are getting into the stage of straw-splitting and etymology generally, I may remark, for the satisfaction of the exact and critical, that *Chambers' Etymological Dictionary* has it that "misrepresent" means *to represent incorrectly*, and that "represent" means *to describe*. According to *Chambers*, then, I have merely stated that my meaning was "incorrectly described," and that is what I meant.*

Will Mr. Debenham undertake to say that the reporters *always* "*do take down* the speaker's actual words," even so far as photographic gatherings are concerned? Of course, I know that sentences or a whole statement may sometimes be taken down *verbatim*. But, even then, we do not often see the result, as Mr. Debenham himself owns; the words are "condensed." What I thought my words would convey to the intelligent reader is this:—That since the present reports are seldom in the actual words of the speaker, but in those of the reporter, who "condenses" and prunes, so little harm could follow from permitting the *speaker* to use some words he did not actually utter, but which embody his meaning. I am quite at one with Mr. Debenham in acknowledging that the "slip system" is not perfect. Very few "systems" are so; but it seemed to me (and this, I presume, is also the opinion of those who inaugurated the system) that there is more chance of an indifferent or inaudible speaker knowing "what he said" than that the reporters should rightly divine his meaning. Mr. Debenham must not omit to take into consideration the fact that by *his* "system," if a speaker is incorrectly reported (I must not write *misreported!*), he must wait, as in the case to which Mr. Debenham so pertinently alludes, until the next number of the *Journal* before the error or omission can be put right. Which is the greater evil. Let us form our own opinions and state them, if we will, amicably.

Mr. Debenham will excuse me if I suggest that writing of the "appalling task of digesting and replying" to my letter does not come fitly from himself. He must remember that on the last occasion I had no fewer than *six* different writers' statements to deal with, and I did not appear to wish to pass over or to avoid replying to all the statements put forward. Does not Mr. Debenham write at nearly or quite as great length when dealing with a *single* writer or controversial subject? And I do not blame him. Most writers worth reading will like to make a complete statement satisfactory to themselves; it is hard to omit any point which may seem to elucidate one's meaning. Why is there not more forbearance and fellow-feeling? I do not advocate "honest statements" of *this kind;* the bluntness of the Quaker to me seems unnecessary. There are some things one may fitly think but cannot with civilised decency express. Still, the fault is but too common, and we are few of us *quite* free from it. Mr. Debenham raised another matter into which I have not space in this letter to enter.

I cannot for the life of me conceive why "A Member" finds fault with me for not leaving the main question and for not modifying my previous arguments. Surely "A Member" might perceive that I had enough to do to disentangle my words and to represent them clearly after the mauling they had received. Besides, surely a man with many or "new arguments" has often not *one* to stand upon. I take my stand upon my original statements, elucidated as they are by my subsequent letter to this Journal. I do not think "A Member" is just in writing that my letter is "an extension of what *was* said for the purpose of explaining what was *intended* to be said"—at least not in the sense he means. *My letter was plain enough and perfectly grammatical, and need not have been misunderstood.* I did not attempt to make it "plain enough for the meanest comprehension" until I found I had to waste space by doing so in these columns. "A Member" does not state how the Council could "come down" upon him had he backed his opinions by his name. Such a matter would be beyond the cognisance of the Council as a body, and I much doubt whether any member of it would attempt or wish to be "down on" any ordinary member

* I find I must reply to a portion of Mr. Debenham's letter.

† These words were explained most fully in my letter published in the same number (July 11th) in which the editorial note to which I refer appeared.

* Mr. Debenham *himself* states (June 20th) that "on more than one occasion" he has been *misrepresented* in the "corrected reports." Therefore "I thank thee, Mr. Debenham, 'for teaching me' the significance of 'this word.'" But ponder, Mr. Debenham: "misrepresentation is a *serious* charge." Thus are we "hoist" with our "own petard!"

who made general and perfectly legitimate proposals. Personal attacks would, of course, be resented; and some of the writers do seem to have been "sailing rather close to the wind." No wonder, under such conditions, they prefer to conceal their names! "Arguments" of the kind they bring forward may very fitly be classed with the action of those who—to use an "elegant expression"—quite as "elegant," though, as many of the anonymous ones—"heave half a brick" as a "clincher!"

And now, I hope, I have done. Whether I am alone in my views on this matter must remain an open question; since all with any knowledge of human nature will be aware that the tendency of men is to state their disagreements rather than their agreements. Many will combat the statements of a writer; scarcely any will back him up, even though of the same mind with him. However this may be in the present case, I have the satisfaction of having openly, honestly, and courteously stated what I thought. In my subsequent letters I have endeavoured not to be offensively personal (under rather strong provocation; those making attacks under cover of *noms de plume* must, I presume, expect something rather "muddy"). Let the same spirit guide others in controversies of this kind.—I am, yours, &c., HERBERT B. BERKELEY.

July 21, 1884.

[We gladly acknowledge Mr. Berkeley's kindness as a contributor in years gone by, and trust that in the future, when he may have the results of any practical experiments to communicate, he will do so with his old freedom.—EDS.]

Notes and Queries.

J. C. (Southport) makes a practical suggestion of considerable value. He says:—"I find that the mercury intensifier is greatly improved in my hands by using, instead of ammonia, a saturated solution of sulphite of soda diluted to one-half."

T. P. B. wishes information concerning the best means of recovering the silver from emulsion that has been fogged.——Let him convert it into thick pellicle and treat it with hyposulphite of soda, afterwards precipitating the silver by sulphide of potassium.

J. G. asks:—"How is it, when intensifying with bichloride of mercury and afterwards with ammonia, I get a very brown stain on the negative?"——In reply: The stain is caused by the mercury not having been removed from the film by washing previous to applying the ammonia.

S. D. L. inquires whether we have observed opal plates coated with chloride of silver emulsion for printing-out become discoloured after keeping two or three months.——In reply: We have seen plates of this class which contained a large excess of free nitrate of silver, and which, perhaps in consequence of this, did discolour. The remedy for or prevention of this must be relegated to the larger subject connected with permanent sensitised paper, to which it is analogous.

"Is there any way by which I can tone albumenised prints by sulphur, as an experiment?—R.S.A."——We reply: Let our correspondent fix the prints upon removing them from the printing-frame, and then immerse them in a solution of hyposulphite of soda to which have been added two or three drops of sulphuric acid. This will cause them to become rapidly toned, after which wash thoroughly. The prints treated in this manner are sulphur-toned. The same effect may be produced by transferring the print from the hyposulphite fixing bath to a solution of alum.

A CORRESPONDENT says:—"How can I test the water-resisting power of the following varnishes on gelatine negatives:—(1) Red shellac varnish, (2) white shellac varnish, (3) ordinary composite negative varnishes, (4) copal varnish, (5) the mixture, and in what proportions, of any of the preceding varnishes with collodion? Furthermore: why is it we never read of the use of gum copal in formulæ for negative varnishes? Is placing a drop of water on a varnished negative, and watching whether it makes a film swell up, or how long it takes to effect an elevation, a good test of the water-resisting power of a varnish? and what varnishes are known to bear this test?

J. GEORGE GIBSON inquires—"(1) What is the cause of central flare?"——Answer: A combination of reflection and refraction, in consequence of which an image of the diaphragm is formed on the plate directly opposite the lens.—"(2) What is the best camera (make and size) and lens (make and size) for an amateur to possess who wishes to do pictures for the photographic exhibitions?"——In reply: All depends upon the nature of the pictures our correspondent wishes to "do." If he decide upon *carte* portraits, a *carte* lens and camera will be the correct implement for him to employ; but if 12×10 landscapes be preferred, then the services of a 12×10 camera and landscape lens must be brought into requisition. In what department of photographic practice does Mr. Gibson think he possesses strength?

GEO. BARCLAY writes:—"In the novel, *Ready-Money Mortiboy*, by Walter Besant and James Rice, I find a somewhat interesting and far-from-uninstructive account of the manner in which oil paintings are treated so as to render them 'old.' But there is one secret that has not been divulged by the clever authors, which is the way by which the paint of even a new picture may be cracked all over in a few hours by the application of a certain something which is applied by a brush at night, and by which in the morning the picture is found to be a network of thin cracks. This substance, we are told, is one which we have 'all eaten times without number.' Can you, Messrs. Editors, inform me what is this substance?"——In reply: We are short of the necessary knowledge connected with this subject; but possibly some reader who knows will impart the information.

Exchange Column.

I will exchange a victoria camera and lenses, which takes four on a quarter-plate, for a good 5 × 4 or half-plate group or view lens.—Address, THE AMERICAN PHOTOGRAPHER, Swanage, Dorset.

Wanted, a landscape background, in exchange for three gem lenses, a *carte* cameo embossing press, a quarter-plate camera lens, and a tripod.—Address, FRED RUBRA, Stony Stratford, Bucks.

I will exchange a good bicycle, in perfect condition, for a good 8 × 5 view lens, Ross's rapid symmetrical preferred, or a good whole-plate camera.—Address, CYCLE, care of H. Greenwood, 2, York-street, Covent-garden, W.C.

I will exchange a good cabinet lens and camera (bellows-body) for a whole-plate lens and camera by a good maker and in perfect condition; difference in cash.—Address, ARTIST, care of Miss A. Ledgard, Lee Green, Mirfield, Yorks.

I will exchange a half-plate camera and lens of good make, also slides and stereoscopic camera and lens by Lerebours, and camera by J. J. Pyne, of Manchester, for a fifty- to fifty-two-inch bicycle or tricycle, with ball bearings, and in excellent condition.—Address, A. E. SMITH, 39, Trafalgar-road, Burnley, Lancashire.

I will exchange a studio tent, 12 × 8 feet, new condition, excellent half-plate portrait and view lens, about seven and a-half inch back focus, and a capital dark tent forming travelling-case or table. Wanted, Ross's portable symmetrical, No. 3 or 4, also cabinet or larger size rolling-press.—Address, PHOTOGRAPHER, Oxford Studio, High-street, Cheltenham.

Wanted, a camera, bellows-body, for plates 12 × 10 or 14 × 12, with two or three double backs, and rectilinear lens for plates 14 × 12, in exchange for a new rolling-machine, 20 × 16 or 24 × 18, compound gear, planed iron beds, mirror-polished steel plates, for hot or cold rolling, value £12 and £14 respectively.—Address, PERFECT BURNISHER WORKS, 14, St. Ignatius-square, Preston.

Wanted, a 10 × 8 or $8\frac{1}{2} \times 6\frac{1}{2}$ camera with double slides, and Dallmeyer's rectilinear or Ross's rapid symmetrical for size of above plates, in exchange for a Coventry rotary tricycle, in good condition, ball bearings to all parts, including pedals and all extras for carrying photographic apparatus, cost over £22; can be seen after six p.m. any day at the following address:—E. JAMES CHESTERMAN, The Rise, Endcliffe Vale-road, Sheffield.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPHS REGISTERED.—

Edwin Iddo Ellery, 96, Pydar-street, Truro.—*Four Photographs of Dr. Wilkinson, Lord Bishop of Truro:* also *One Photograph of Dr. Wilkinson with his Chaplain, the Rev. Maxwell-Lyte.*

NOTICE TO SECRETARIES OF SOCIETIES.—It is earnestly requested that when proofs of reports and papers read at the meetings of societies are forwarded to the Secretary they may be returned at once to our printing office, 43, Harrington Street, Liverpool, so that any corrections may be made before the report or paper is published. We last week received at the moment of going to press a proof of a paper which had appeared in our previous issue, and which bore a very large number of corrections (many of them of a trivial character), all due to the copyist of the original MS.—not one to the printer. We are at all times anxious to do our best to secure correctness; but when the proofs are sent out and not returned we are bound to assume that the original MS.—especially when plainly written as in this case—is accepted as accurate.

ROSS.—Yes; with very rapid plates the lens mentioned can be successfully employed with a drop shutter on tolerably well-lighted subjects.

W. G. GILES.—The remedy is very simple. Reduce the pyrogallic acid to one-half and increase the bromide to double. If you do this your difficulty will be overcome.

MISS LEVEN.—We know little or nothing of the process in question; but from the little we do know we cannot recommend you to have anything whatever to do with it.

A. Z.—Unless you are in possession of a lathe we fear you will completely fail. Why not take the apparatus to some working optician, who will, doubtless, do all you require, and properly too, for a very trifling sum?

H. W.—Good ordinary work—nothing more. The landscapes are, on the whole, better than the portraits. The latter lack refinement and artistic treatment. The lighting is not particularly good in the portrait subjects.

S. J. W.—The acetate of soda toning-bath will yield tones like the print forwarded; but the negative from which the print is made must be strong and vigorous. No toning-bath, by whatever formula it is made, will produce such tones unless the negative be suitable.

J. T. CUBBERLY.—Probably the new toning-bath was put into a dirty bottle, or the water with which it was made contained something that reduced the gold to the metallic state. The presence of a small quantity of iron would fully account for the bright, metalled particles.

R. F. W.—It is impossible to say the cause of the spots, inasmuch as you give no information whatever as to how the print was produced. From the appearance, however, of the picture it looks very much as if it had been splashed with something which has caused the print to fade when it has been touched.

J. J. H.—Received. In our next.

ANDREW MCCRAE.—We have not time to go through the whole of the calculations; but, from one or two that we have worked out, we judge that all are correct. If, therefore, your measurements are accurately taken the calculations with regard to the exposing will be fairly correct.

ROBT. J.—The proportion of chrome alum to the gelatine given is quite correct, but not for the particular description of gelatine you have used. For that kind two-thirds the quantity will be ample. The "clotting" is due to the excess of alum used for the particular sample of gelatine employed.

H. W. L.—You appear to have treated the fixing solution in the orthodox manner, unless you have added too great an excess of the sulphide. Of course the amount of silver recoverable is dependent upon the proportion of bromide of silver contained in the emulsion with which the plates are coated, and not upon the amount they cost.

T. W.—Judging from the appearance of the print, and having nothing further to guide us, we should say that your trouble arises from an insufficient quantity of gold in the toning-bath. However, the print is so badly sulphuretted, and shows other evidences of careless manipulation, that we cannot say for certain that this really is the source of the trouble.

W. H. B.—We, unfortunately, can afford you no assistance whatever. Your only remedy, if you think you have a good case, is to fight the matter out in the County Court. We are in no way responsible for the advertisements that appear in our pages. Possibly had your remonstrance been couched in different terms to those employed, the reply might have been of a different character.

J. LOCK.—The cause of the black spots in the carbon transparency is that the tissue has been splashed with some fluid which has induced insolubility in the gelatine. That it has been splashed with a liquid is clear, as in one or two places it can plainly be seen that it has run downward and produced a "tear." It is impossible to say at what stage the injury occurred; but we imagine it must have been between the sensitising of the tissue and the printing.

OMEGA (Leeds).—Many, like yourself, have experienced the same difficulty in sensitised carbon tissue during the recent hot weather. The reason of the "black coating" dissolving in the bichromate bath is that the solution was at too high a temperature. During very hot weather the sensitising bath must be cooled artificially by the addition of a few lumps of ice. The temperature of the solution should not exceed 55° or 60° for successful working. Several articles on hot-weather troubles in carbon printing have appeared in former volumes.

A LITTLE AMATEUR.—We can scarcely recommend you to purchase the apparatus in question, although the price is certainly very low. It will, doubtless, take good pictures, but it is very antiquated and heavy. It was considered very light and portable at the time it was made; but during the last twenty years great improvements have been made in portable outfits. Probably a modern camera of similar dimensions—or rather for the same size of picture—would not weigh more than one-half, be far less bulky, and be more efficient. The lenses also, being of the old landscape form, are very cumbersome. That the apparatus is really good the maker's name is a sufficient guarantee. If weight and portability be not an object with you, then the outfit will answer your purpose exceedingly well.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—The first outdoor meeting of the season will be held at Hampstead Heath tomorrow (Saturday), the 26th instant. Tea at the "Bull and Bush Hotel" at six o'clock.

QUITE A TAKE IN.—Photographer: Well, Pat, will you have yourself "taken" today? We won't keep you more than five minutes. —Pat (with a lively recollection of a police cell): Begorra, thin, the last time I was taken, sure I was kept in all night, so I was.—*Fun.*

POPULARISING PHOTOGRAPHY.—We have received from Mr. F. A. Bridge his new prospectus of lectures discriptive of photographic tours and scenery illustrated by means of the "tridiaphanon"—a triple lantern by which the photographic illustrations will be exhibited as dissolving views by Mr. William Brooks, who in this acts as the colleague of Mr. Bridge. Some idea may be afforded of the character of the entertainment when we say that the series includes Antwerp, Brussels, Bruges, and Ghent; Holland and the Hollanders; the castles and abbeys of England; the lakes of England and Ireland; together with many examples of instantaneous photography. We have no doubt that our friends will secure during the forthcoming season all the public approval they so richly merit. We have a vivid recollection of the great attractiveness of the exhibition the same gentlemen recently gave in the large hall of the Society of Arts.

PHOTOGRAPHING ACTORS AND ACTRESSES.—Mr. Sarony, the famous New York photographer, has been giving his experiences of actors and actresses before the camera. The ordinary actress, he says, is the worst nuisance. She is never satisfied, and always has ideas of her own which are as a rule detestably inartistic. "Of all my sitters Bernhardt was the best. She was terrible in one way—always late for her appointments. She would rush in three hours after time, but apologise in such a pretty way that I had to forgive her. Then she not only knew how to pose, but when I got excited she felt the reflex of my emotion, and so would gradually assume the expression I desired, and a grand picture was the result." Mr. Irving was too busy to sit—much to the gushing photographer's sorrow. Booth has not cared to sit much. He seems bored always when the theatre is mentioned, and does not care to be photographed at all. Miss Terry's tantalising ways tried the ecstatic Mr. Sarony's patience sadly. "She is simply the best subject I have ever had, but the most tantalising. I was in despair when she was in my studio; every movement was a revelation of grace, every gesture a picture, and every expression a delight. I was crazy with pleasure. 'There, there! for Heaven's sake! stay in that position for three seconds'! I would cry; but the next instant she had moved, and some other lovely pose was the result. Her walk across the room was a succession of pictures, but no sooner did I implore her to remain for one moment in any of the positions she assumed than it was gone."

CURIOUS CASE.—At the Liverpool County Court, recently, before Mr. T. E. P. Thompson, judge, Mr. A. Vandyke, photographer, carrying on business at Bold-street, Liverpool, sued Mr. Geary, of Birkdale, Southport, to recover £3 3s., the agreed charges for an opal enlargement of the figure of a lady made from a glass picture at the defendant's request. Mr. H. F. Neale, who appeared for the plaintiff, stated that the picture was well executed, but the defendant rested his contention of the claim upon the fact that no proof had been supplied to him. Correspondence was then read in which the defendant alleged that he was dissatisfied with the picture, as he had bargained for a proof, and the plaintiff had agreed that he should not be bound to accept the finished portrait unless he (defendant) approved of it.—Evidence having been given for the plaintiff, Mr. Broadbridge, who appeared for the defendant, in cross-examination of Mrs. Vandyke, elicited that she might have said the defendant was not bound to take the portrait unless it was satisfactory.—Mr. Broadbridge then called the defendant, who said he objected to the picture because it seemed to show the lady represented as a sufferer from liver complaint—(laughter)—and there was a cadaverous expression about the face. (Renewed laughter.) He also said Mrs. Vandyke said he was not bound to accept it unless satisfied with it, and, being dissatisfied, he repudiated the contract.—Mr. Neale contended that the fact of a proof not having been delivered was not an indispensable condition to the bargain, and that the mere crotchet of the defendant would not entitle him to succeed in the absence of evidence that the picture was not a good production.—His Honour, in giving judgment for the defendant, said he was sorry for Mr. Vandyke, as he (the learned judge) was surprised that such an excellent picture could be produced from such a vague original; but as Mrs. Vandyke had admitted that the bargain with defendant was that he was not bound to accept unless satisfied with the picture, he was reluctantly compelled to give judgment for the defendant, at the same time expressing an opinion that Mr. Vandyke had been very badly used.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
July 29	Bolton Club	The Studio, Chancery-lane.
,, 30	Photographic Club	Anderton's Hotel, Fleet-street.
,, 31	London and Provincial	Masons' Hall, Basinghall-street.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician,
For two Weeks ending July 16, 1884.
THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

July.	Barometer.	Wind.	Dry Bulb.	Wet Bulb.	Max. Solar Rad.	Max Shade Temp.	Min. Tem.	Remarks.
3	30·02	W	69	63	117	85	61	Hazy.

JOURNAL OF PHOTOGRAPHY.

No. 1265. Vol. XXXI.—AUGUST 1, 1884.

STUDIOS WITH PREDOMINATING TOP LIGHT.

The best manner in which to ameliorate the effects of an overpowering top light in a studio is one of great importance to portrait photographers, and has at various times received much consideration. Many studios are surrounded in such a manner, and so compactly, by the dense, unreflecting walls of adjacent buildings as to have virtually all the side light shut out, thus permitting the top light to have an undue predominance, the result being portraits with heavy shadows. The evil in question is more prevalent when the studio is erected on the ground or parlour floor, or in a garden surrounded by trees, than when it is situated on the roof of a tall house.

A method which we have frequently recommended in order to diminish the relative intensities of the top and side lights under the circumstances at which we have hinted, and to tend to their equalisation, is the one, now well known, of glazing the sides of the studio with ground glass, by which the previously dark sides—dark in consequence of an unlighted side of a house extending upwards to a great altitude with the light at an angle of forty-five degrees—become lighted.

As to the angle at which the light should fall upon a sitter so as to illuminate him properly we shall not here advert, that being a little outside of our present inquiry, which strictly relates to the reducing of the contrast between top and side light, when the circumstances of the studio erection are such as to give a considerable preponderance of the former owing to there being very little of the latter. We are, however, very well aware that the angle of forty-five degrees to which we have made allusion is one which has been determined by artists as that from which the dominant light should come; but we now desire to increase the power of our side light, which, of course, is very much lower than the angle mentioned. It is not only well, but necessary, to have a "giant's power" in lighting, although it is not always necessary or wise that it should be so used.

We have spoken of the substitution of ground glass for plain glass as the medium through which side light should be admitted into the studio when the external surroundings are of a dark or non-reflecting colour, and when, without subsidiary aid, a portrait taken in such a studio would prove defective from the dominance of the top light. This the ground glass ameliorates by receiving light from that portion of the sky which overtops the obstructing medium, and giving it off by reflection or refraction from the innumerable rugosities composing its granulated surface. This constitutes a great gain in the illumination of the studio by side light; but from its very nature it is inferior in its power of deflecting light to any system in which reflection, pure and simple, from a polished surface is employed. The great value of a common mirror for this purpose has been recognised by many who employ what are termed "daylight reflectors" to illuminate places to which the access of light would otherwise be nearly impossible.

If in a side window looking upon a dark wall or house—which, from the sitter's point of view, would be seen as such, and consequently possess no value for illumination—if in such a side light a sheet of ground glass be fixed so as to prevent the wall from being seen, the obstruction of vision will be found accompanied by highly-illuminating properties. This, it may be remarked, is not peculiar to ground glass, as any diaphanous material, such as tissue-paper, will answer a similar purpose. But when, instead of such radiating agents, a silvered glass mirror is substituted, and placed at such an angle as to reflect the light of the sky, then the brilliancy of this portion of the side light is so greatly enhanced as to render it almost equal to the pure light of the sky.

In order to test this point we have had constructed a miniature studio glazed on the side as well as the roof, but having the side light obstructed to the degree of which we have already spoken by suitable erections. Upon placing a plaster bust inside we found that the top light was sufficiently powerful to give an altogether objectionable depth to the shadows. A sash previously filled with plates of ground glass was now inserted in the side instead of the plain glass. Under this arrangement, while the dominant top light was not interfered with or modified in itself, it became so in a marked degree by contrast; for the portions of the figure previously in deep and harsh shadow were now well lighted. Having carefully noted the effect obtained by the substitution of the ground-glass side for that of plain glass, we removed the former and substituted for it a number of slips of silvered glass mounted like the laths of a venetian blind, the arrangement being such as to cause them, as a whole, to form a screen by which no *direct* side light was admissible at all, but by which the light of the sky was reflected horizontally, or nearly so, in an apparently unbroken mass. The effect was not a little singular; for, whereas previously the top light dominated, it was now not only equalled in force by that from the side, but was even subordinated.

As a practical deduction from the experiment described, we would advise those whose studios have an excess of top light—and who, as a consequence, obtain portraits in which the shadows are heavy by contrast with the lights, which are somewhat "patchy"—to equalise the lighting first of all, and by way of experiment, by obtaining the thinnest white tissue-paper that is sold and fastening it upon the side lights at such a height as will shut out from the sitter's view all the dark wall, the presence of which we have assumed. This will effect a marked difference in the lighting. If it prove sufficient, it only remains to supply its place with sheets of ground glass when leisure or circumstances permit. If, however, the contrast be still too great, and it cannot be lessened by screening the top light without unduly increasing the exposure, recourse must be had to the venetian blind system of reflectors, the power of which is undoubted, as we have shown, and the cost very much less than could have been anticipated; for the cheapest quality of glass that is silvered will answer this purpose quite as well as a better and more expensive sample.

By way of varying the experiment described we have had constructed four thin boards, each about a foot wide, which we have had fastened together at the ends and slightly apart from each other, on the principle of hanging book shelves. These have been covered with sheets of tinfoil and suspended so as to form an angle, by which the non-effective light from the wall is debarred admission and the bright light from the sky reflected instead. This causes an admission of light into the studio very greatly in excess of that obtained by radiation from the ground-glass panes, and may, therefore, be recommended as more advantageous. Without, however, having made trial of it, we imagine that if the boards had been covered with white paper of perfect purity instead of tinfoil an amount of side light would still be obtained equal to that emitted by the ground glass.

PRINT-WASHER FOR *CARTE* AND CABINET PRINTS.

In accordance with our promise of last week we give drawings of a print-washer which, as we stated, we have seen in action on several occasions, and found the washing and draining to take place regularly and effectively, and evidently need no interference from the moment the pictures are placed in the apparatus and the tap turned on until the time arrives for them to be taken out and dried. It is upon this latter characteristic that so much of the value of such a machine depends. When a few hundred prints have daily to be put to wash there is every probability that when special hand-work has to be called into play the work will, if not usually, at anyrate occasionally, be shirked, to the detriment of the prints and the injury of the artist's reputation; while the thousands which must be the "output" of some establishments might well entail the necessity for one *employé* being detailed to the sole duty of washing prints.

Quite recently we saw a very striking instance of the difference in keeping powers of prints produced under different conditions. A gentleman who had spent four years in Ceylon since last we saw him told us that of two lots of *cartes de visite* which were taken by different firms a week or two before he started, and which he had taken out with him, one set faded before he had been in the country a month, while the other was as good when he left Ceylon after his four years' stay as when he first took them out. There is no question here as to which of the two houses would secure our friend's business orders whenever he required further pictures; and there is little question, also, that varying modes of washing was the most likely cause of the vast difference shown in the keeping powers of the two sets of pictures.

One important point must always be kept in view in using either the washer which we now bring before our readers, or one of any other construction: it is that in all cases it is most desirable not to allow the prints to remain for many moments in contact with a small quantity of water until the first (the greater) portion of the fixing solution is got rid of. Although a good washer will quickly bring about the desired end, it may be facilitated to a still greater extent by a proper treatment of the prints in the first stage. They should not be taken out of the hypo. in a mass and thrown in a heap into the washing water; but should be taken up one by one, dipped in a pre-

FIG. 1.

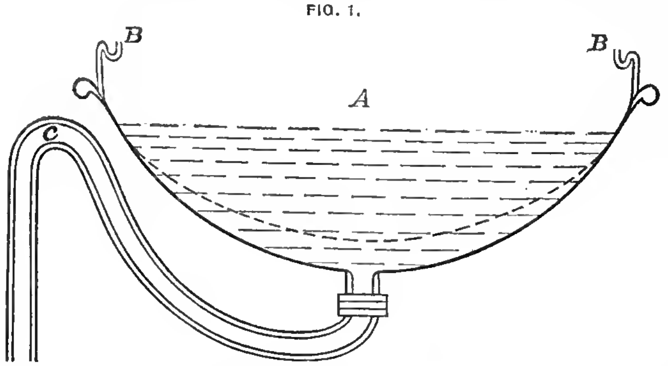

Fig. 1. Represents a section of the trough, the supports being left out to avoid confusion; a strong wooden framework of the simplest construction serves for this purpose. The trough A is made of zinc externally, and has an inner false bottom, shown by the dotted line, carefully fitted and soldered in its place, so as to form a continuous curved surface. To give stability the rim is strengthened by being curved over a thick iron wire in the usual manner. The syphon C is of three-quarter inch bore, is slightly flattened at the curve C, and its outer leg made to line a little from the perpendicular, the end being directed slightly inwards. These two points obviate the dribbling action which, with some forms of syphon, prevent any complete emptying, through merely acting as an overflow.

liminary washing water with a to-and-fro motion, and afterwards passed into the washing trough; then, if the trough be a good one, there need be little fear as to their permanency so far as can be effected by the mode of washing.

In the trough under consideration provision has been made for the following conditions:—First, a periodical change of the water in which the prints are immersed, so that whatever salts are taken from the prints may be removed at once from their vicinity. The action of washing water being chiefly osmotic it follows from the known law of diffusion—the greater the difference between the densities of two solutions the quicker will the diffusion take place—that the hypo., when slight in quantity, stands a far better chance of being removed from the paper when it is surrounded by water than by a weak solution of hypo. This change is effected by the well-known syphon method.

Secondly, such a mode of working as shall ensure the free penetration of fresh water to the surfaces of each print. This is brought about by the arrangement of the jets. When they are arranged as in the drawing it will be found that the water as it flows into the trough gradually assumes a rotary motion, and the prints are carried with it; but, instead of their forming a solid mass in the centre of the dish, as happens with a single jet, each print will be seen to pass along or over its neighbour, never adhering for long together. The jet *e* shown directly pointing to the centre is

FIG. 2.

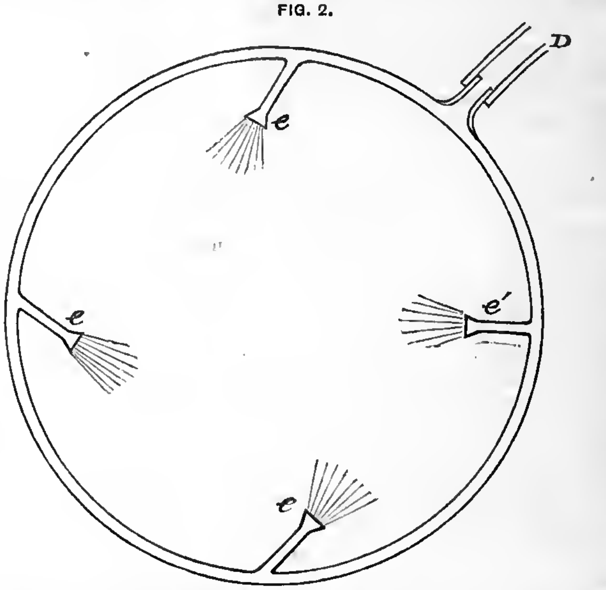

Fig. 2 shows the mode of conveying the water. It consists of a ring of metal tubing, out of which spring four jets, *e*, of narrow lead pipe, flattened at the exit end so as to spread the water out as a flat jet. The exact form of jet is not essential, nor the exactly flat shape; a little management with a pair of pliers and a pocket knife will enable anyone to adjust them for himself. D shows where the water enters the ring by a side pipe attached by a piece of strong rubber hose to the tap, where it may remain as a fixture or not, according to convenience. The jets being of soft metal, the angle at which they are placed can be easily altered if they are found to be not quite right. The straight-out jet *e'* should deliver the water a little past the centre of the trough. B B in *fig.* 1 are four supports formed of pieces of stout sheet lead, bent as shown, to receive the ring of jets. The washing is started by turning on the tap, when the water will flow from the jets and give a broken rotary motion to the water, the jet aperture being adjusted so as to avoid dashing too strongly on the prints.

mainly instrumental in producing this effect, and it is very interesting to note this change of action brought about by altering the pitch of the various jets. If they are all made to point in one direction the prints will go swirling round, but will soon collect in a heap, which will not readily, if at all, break up after hours of washing, whether the trough be filling or emptying.

It is evident that the pressure at which the water enters the washer will materially affect the mode of action; hence, to ensure the regular action of any automatic or syphon washer, it is evident that a water supply from a storage tank would be most regular in action. The drawings are almost self-explanatory, as the whole arrangement is so simple, and, indeed, as we have said, differs only in detail from a multitude of other similar pieces of apparatus. We may say that it is advised that the prints be taken from the water when the trough is filling or when the water is turned off while filling, as there is said to be a risk of tearing the prints when they are removed while the trough is empty or emptying.

Finally: we may state that we are informed that the particular apparatus here figured has been in use for over a dozen years, and has required no repairs beyond a fresh piece of perforated zinc for the false bottom.

COLD-AIR MACHINERY IN PHOTOGRAPHY.

At the conclusion of the article on *Cooling and Ventilating*, in last week's issue, we incidentally mentioned that it had been our intention on commencing it to make some allusion to the apparatus which is now so extensively employed for producing air of an intense coldness, and its application to purposes in connection with photography.

We, however, propose to do so now—not with the idea (as the summer has so far advanced, and the excessive heat we had at the commencement of it has considerably moderated) that our suggestion will be put into practice this year, but that it may possibly receive consideration for next season, or may, perhaps, be made available in tropical climates where ice is not procurable. Every dry-plate manufacturer on a large scale knows quite well the large expenditure that has been necessary for ice during the last few weeks. In some of the large establishments, we are informed, the consumption of ice has amounted to tons weekly. Of course this means a considerable addition to the ordinary cost of production. Apart from its costliness the method of cooling by ice is not altogether satisfactory, as it acts only locally, and the cold produced cannot be easily diffused through a considerable space unless, indeed, a very large quantity of ice be employed.

Hot-weather difficulties, be it understood, are not alone confined to dry-plate manufacture, as they are experienced to a similar extent in every branch of photography having gelatine as its base. Woodburytype, stannotype, collotype, carbon printing, and analogous processes have all been worked for some time past under the greatest difficulty and inconvenience—some of them, indeed, being only practicable during the night or the early hours of morning.

In the Health Exhibition are to be seen in operation several different forms of machines for producing intense cold—say a temperature from 40° to 90° below zero. These machines are being at the present time extensively employed on the vessels which transport fresh meat in a frozen condition from the Australian and New Zealand colonies. Now these machines can be made available for many purposes in connection with photography, which are now dependent upon ice as a refrigerating agent.

The theory of all "cold air" machines (it may be mentioned for the benefit of those readers who are not familiar with the subject) is based upon the fact that heat and work are convertible terms, and it is put in practice as follows:—Air is compressed into holders to the extent of some sixty to one hundred pounds to the square inch. This compression generates a considerable amount of heat, which is then absorbed by cold water circulating in tubes surrounding the holders. When, by this means, the air has been cooled down to the temperature of the water, it is allowed to expand. The work done in expanding absorbs all the heat left in the air, and, consequently, it is left in an intensely-cold condition. This cold air is discharged into closed chambers in which the meat, or whatever may require cooling, is placed. As soon as the requisite degree of coldness is produced in this chamber the machine is "slowed," so that the atmosphere is maintained at an equal temperature without an unnecessary expenditure of power.

It is easy to see that an apparatus of this description would be of immense service in a dry-plate manufactory during the summer season; in the cold chamber for rapidly cooling the emulsion after cooking—a great advantage during thundery weather—and for preserving it afterwards; also for supplying a current of cold air to a shallow chamber, which may be constructed to surround the slab upon which the plates are put to set. The rapid setting of the emulsion is, of course, a great desideratum, particularly when the plates are coated by machinery; for it is manifest that it is useless to coat the plates rapidly unless the setting of the emulsion can be effected at the same rate. Fortunately, for gelatine workers, it happens that when the gelatine has once set it requires considerably more heat to again liquefy it than would suffice to keep it fluid in the first instance. Hence, if the emulsion can be thoroughly gelatinised, there is little fear of its running afterwards.

A cold air machine would be invaluable in a Woodbury or stannotype printing establishment. If the presses be put into a chamber of the intensely-cold air supplied by these machines they will quickly become cooled down to such a temperature that it will take several hours, in a moderately-warm atmosphere, for them to regain sufficient heat to render them unworkable. By having two sets of presses, one set can of course be cooling while the other is in use. In collotype printing, too, they would be of service in a similar way; for if the plates were placed for a time in the refrigerating chamber they would soon become exceedingly cold. Glass being one of the best non-conductors of heat, and the plates thick, they would require a considerable time to regain sufficient heat to cause inconvenience in working. As in the Woodburytype process, so two sets of collotype plates might be kept in use—one cooling while the other was being printed from.

It can well be conceived that, in the manufacture of carbon tissue during excessively hot weather, these machines might prove of great service. The chief difficulty in the manufacture of carbon tissue in an elevated temperature, it is well known, is in getting the pigmented coating to gelatinise; but if the paper were made to pass through a shallow cold-air chamber immediately after being coated this difficulty would be surmounted.

Unfortunately these machines are, at present, somewhat expensive, the smallest size costing something like one hundred and twenty pounds; and it also requires a gas or other engine of two-horse power to work it. But the cost should not prevent its employment in large establishments, considering that excessive heat often completely stops operations as well as occasions considerable loss of material. When once the outlay is made and the apparatus installed it can be worked at a merely nominal expense, costing only about twopence or threepence per hour for gas, supposing a gas engine to be employed—a very different outlay to that for ice for refrigerating purposes, when large spaces have to be cooled.

The size of machine here alluded to is much larger than is actually required for the purpose suggested, it being really sufficient to preserve several tons of meat in a frozen condition; but at present it is the smallest in the market. It is quite possible, however, should a demand for them arise, that cold-air machines will eventually be constructed in smaller sizes, which will prove a great convenience for many purposes besides that of photography.

Truth has been offering a series of prizes for "Suggestions for Original Poses for Photographic Sitters," and recently treated its readers to a few dozen specimens, which are described as "good and otherwise." From one or two average examples it will not be difficult to believe that the bulk of the attempts are rather "otherwise" than good. "A lady on a tricycle, shooting over left shoulder a Parthean glance at a gentleman," &c., suggests one; "place the 'sitter' slightly in advance of a group of niggers (decently attired) in order to create a contrast," directs another; "asleep, as then there would be no bother in fixing oneself," is the idea of a third aspirant to honours. The only fairly decent suggestion is to photograph a professional beauty *with* her husband; but, on the whole, the efforts at amateur posing are singularly disappointing.

We perceive that the weekly Chicago *Eye*—one edition of which was formerly devoted to the interests of photography—has now become a photographic weekly paper altogether, under the control of Mr. Charles Gentilé, the previous editor of the photographic edition. This first weekly American photographic periodical has our best wishes for its continued success.

Those who desire to read a popular exposition of the effects of light upon the health should peruse Mr. R. F. B. Compton's lecture upon artificial lighting, delivered a short time since at the "Healtheries." There is much interesting matter in it, and the question of electricity *versus* gas is rather fully treated, naturally from the electrician's, rather than the gas engineer's, standpoint.

"The various artificial lights differ very widely from sunlight in this respect—that they are all more or less deficient in the rays at the violet end of the spectrum, commonly called the 'actinic' rays, and which most probably exercise a very powerful effect on the system." Again: "But still both classes of electric light are far superior to all others in nearest approaching the white light of daylight, and thus satisfying the actinic action which our bodies demand." So Mr. Compton states; but it will be observed that this portion of his lecture, from which we might have expected useful information as to the effect of the usual dark-room illumination, is all pure assumption, without a particle of proof or reference to authority, and is, further, quite contradicted by the latest investigations on the effect of the various rays of the spectrum upon life functions. The restricted application, too, of the term "actinism," which has long been shown to be a quality attaching to a particular chemical, rather than the property of a special portion of the spectrum, will not commend the lecture to thinking photographers. Still, as a whole, it is both instructive and readable.

It has often been stated that no light penetrates to the lowermost depths of the ocean where the plummet will indicate thousands of feet; but recent investigations must cause that opinion to be modified, and we may expect even yet to have photographs of submarine life of a very interesting character. A writer in *Science* has lately shown in a very conclusive manner, from the observations made upon marine animals drawn up from the bottom of the ocean, that the power of seeing must be possessed by these beings, and as a matter of course there must be light to see by. Most of the fish inhabiting these great depths, to leave which and ascend to shallow water would involve their death, are provided with eyes—some larger than, and others similar in size to, their brethren of the upper circles. Many of them are very bright in colour—a brightness which the writer referred to ingeniously shows is protective. The fauna of those portions of the earth with which we are brought into more intimate contact are usually dull grey and brown in colour, but these deep sea fish are brilliant orange and orange-red. "These facts indicate that the deep sea is illuminated by sunlight that has passed through a long stratum of water, and therefore lost all the red and orange rays by absorption. The transmitted rays of light could not be reflected by the animals referred to, and therefore they would be rendered invisible. Their bright colours only become visible when they are brought up into white sunlight." Hence, though these depths appear so dark to the eye, it is possible that they may possess a power of light that would render the production of photographs with quick exposures by no means improbable. Why should not a camera be let down and panoramic views secured? Who knows what valuable information the camera might be the means of revealing!

What a check on the exuberant imaginations which guide the artists who depict the wonders of the deep such a series of views would be! Photography has played a prominent part in keeping within bounds the travellers' tales of *terra firma*, and the *savants* are at present deeply interested in the photographs brought home by Mr. Joseph Thomson, the leader of the Geographical Society's expedition to East Africa, who has secured many pictures of unusual interest. We may feel quite sure, in advance, that they will depict none of the tailed men, the pigmies, the dwarf troglodytes, or the multitude of other monstrosities with which the early travellers peopled those regions.

The well-known, if not well understood, action of oxygen upon india-rubber bags is touched upon in an article referring to certain occlusion phenomena by Schutzenberger. He says that when the gas is prepared in the common manner, by heating chlorate of potash and oxide of manganese, a considerable quantity of chlorine and oxides of chlorine are carried over from the retort with it, and are not entirely eliminated though well washed with water and stored for a period of two or three weeks in a metallic reservoir in the presence of large quantities of water. Although oxygen so stored may be passed through solution of nitrate of silver, or litmus, or indigo water, and produce no reaction whatever, such as chlorine or its oxides would give, it will yet act upon caoutchouc like ozone. But a very singular effect is seen when this oxygen is passed through a narrow platinum tube at one point; the presence of chlorine is then distinctly shown, the indigo or litmus is bleached, and the silver precipitated.

Our readers may be interested in learning some theories regarding silver held by the Chinese, as set forth in their medical works. Cinnabar (vermilion) takes two hundred years to produce; in three hundred years it becomes lead; in two hundred years more it becomes silver; and then, by obtaining a transforming substance termed "vapour of harmony," it becomes gold! So that if any of our readers would try this marvellous piece of alchemy they can lay down packets of cinnabar instead of pipes of wine to ripen and mature!

Few things are more serviceable in the laboratory than iron vessels lined or coated with glass; but most of the evaporating basins, trays, saucepans, &c., hitherto produced have been glazed with a material so porous and brittle that they have scarcely been worth purchasing. It is, however, stated that a really-serviceable glaze can be produced in the following manner:—125 parts by weight of flint glass fragments, twenty parts of carbonate of soda, and twelve parts of boracic acid are melted together, the fused mass poured on a stone slab, and powdered when cold. This powder is to be made into a thick cream, with silicate of soda solution of 50°. Baumé, and the vessels coated therewith and heated in a muffle till the glaze is melted. This glass is said to adhere firmly to iron or steel.

It is often asked why lens tubes are not made of aluminium instead of the usual heavy brass. As one cause the high price of the aluminium may be quoted, for, though the actual weight of metal required is small in comparison with brass, the actual cost is even then by no means light. Another important objection is the difficulty of soldering the metal together. This difficulty, however, has been recently overcome, according to a statement in the *Comptes Rendus*, by M. Bourbouze. He uses alloys of zinc and tin, or preferably of tin, bismuth, and aluminium, which, he says, "take" upon the surface of aluminium as ordinary solder does upon other metals. He therefore coats the aluminium with these, and any other metal with tin, and then the surfaces may be soldered as usual.

LIME-LIGHT EXPLOSIONS AND THEIR PREVENTION.

The account which lately appeared in the Journal of the explosion at the Drury-lane Theatre determined me to repeat my experiments with the safety tubes or flame extinguishers, in order that there might be no possibility of any mistake in a matter so seriously affecting human life. The result was in every way confirmatory of the conclusions before arrived at, namely, that the protection given by these tubes is complete if they are used in the way directed. A man may easily say that he has succeeded in driving an oxy-hydrogen flame through a slab of plaster of Paris; but this is not to the point, unless he can show that the conditions were the same as those which obtain in the lime light.

Since writing my last paper I have experimented with four different sorts of granules which resist any test I can apply, namely, pumice, binoxide of manganese, slate, and white clay tobacco pipe. I have also again tried two others which stand well with a moderate pressure of the exploding gases, but fail when the pressure is purposely made extreme and the tube shortened to half-an-inch. These are metal filings and rounded particles of flared glass. Why they fail it is not easy to say, unless it be that the filings lie too loosely together and the shape of the beads of glass is not so favourable to resistance; or possibly the *porous* character of pumice and clay may have something to do with their superior efficiency as flame extinguishers.

Of the four first-mentioned substances pumice has this advantage—that it is sold in commerce in the granulated form. Black oxide of manganese is very hard (especially if you choose a sample of the vitreous kind, which breaks with a conchoidal fracture), and it is also comparatively free from dust. Slate and tobacco pipe are both ready to hand, and can be crushed in a few minutes in a Wedgwood mortar.

I obtained from Messrs. Bedford and Steer, wire workers, of Long-lane, Bermondsey, London, a set of all the numbers of wire gauze which they manufacture, from twenty to sixty meshes to the inch, in order to ascertain the best sizes for the screening of the granules. The effect on the pressure of the gas was not so marked as I expected, within certain limits, nor was the difference so great in the power of extinguishing flame. Granules screened by Nos. 30 and 40 stood sufficiently well under a moderate forcing action, without allowing the flame to pass. Taking everything into account I am inclined to select Nos. 40 and 50 as the best sizes. Commercial granulated pumice screened by these two sieves passes almost entirely through the former, and leaves about two-thirds of its weight upon the latter. The remaining third, which passes through

No. 50, contains very minute particles mixed with dust, which would be likely to blow into the burner and choke it up.

I do not find granules screened by the same sieves to correspond exactly in their effect upon the pressure. The flared glass reduces it somewhat more than the slate, and the slate a little more than metal filings or pumice. Again: a perceptible difference can be detected between slate granules produced by scraping with a knife and others got by crushing in a mortar. The former are *scaly*, and lie more closely together than the latter.

Taking pumice as one of the best in reference to the pressure, I find that a hundred-weight and a-quarter on the bag, with a safety tube of three-quarters of an inch long, corresponds very nearly to one hundred weight when no safety tube is used.

The plan which I adopt in determining the pressure is to count the number of seconds a given volume of gas takes in passing through the jet. After a little experience, however, it can be estimated roughly by drawing air through the tube with the breath.

Mr. Broughton's original safety chambers were about half-an-inch long, and this appears to be sufficient when they are full; but if the granules sink down I have known the flame to pass, and hence I prefer making the column of pumice a little longer.

On looking over my last communication I see that the directions for extemporising a safety tube are not sufficiently explicit. The screw caps at the end of the tube are intended to keep the discs of wire gauze from shifting, and if these caps are dispensed with the discs must either be soldered on or fixed by a ring of wire. Unless this be done the explosion in the jet will be liable to force forward the whole of the contents of the tube. Also, it will be advisable to strengthen the disc of sixty meshes by a second disc of twenty meshes immediately in contact with it. If the discs be pushed into the tube to keep the granules in position care must be taken not to push them in too far, or the passage of the gas will be much impeded. A better plan will be to shake the granules well down by tapping, and then to scrape off the excess with a knife, placing the disc of wire gauze on the top or fixing it into the cap.

Only experience can decide how often the tubes will need repairing and refilling. Mine have rusted very quickly; but, then, I have been constantly sending explosions through them, and the after-gas of these ether explosions is very sour and corrosive. The combustion appears to stop short of carbonic acid, and to generate an acid much stronger and containing less oxygen. I advise that the contents of the tube should always be changed after an explosion—not only from this cause, but also to avoid *dust* from the shattered granules, which finds its way into the burner.

I am afraid that my experiments with hydrogen and coal gas are not entirely beyond the reach of criticism, seeing that the gases were not absolutely pure. Yet I think we may conclude, beyond a doubt, that the extinguishing of the ethoxo flame is the more difficult, and that any safety tube sufficient for this will answer also for the oxyhydrogen.

Lantern exhibitors who have ether tanks in which the oxygen passes *through* the ether will do well to change them for tanks with the oxygen passing over the surface of the ether, if they wish to work the safety tubes to the greatest advantage. Not only is there a gain of over thirty per cent. in the pressure, but the light is more steady and free from what Mr. Baker terms "waving." In the old form of tank, when the safety-tube is attached, you can see the flame rise and fall each time a bubble of gas passes through the liquid, exactly as it does in a common gas jet when water has found its way into the pipes. T. Frederick Hardwich.

PHOTOGRAPHY IN THE METEOROLOGICAL OBSERVATORY.

Some months ago I had the pleasure of sending to The British Journal of Photography an account of the waxed-paper process as it is carried out at Stonyhurst Observatory; and today I propose to supplement the previous account by a few words on the argentic gelatino-bromide paper, which has lately been tried here with very promising results.

Having to print two copies of the curves for the barograph and thermograph, one under the other, I found that, when using two waxed papers, the curve on the paper next the cylinder was not very satisfactory, from under-exposure; so I substituted in its place a sheet of argentic gelatino-bromide paper, still retaining the waxed-paper for the outer sheet. This arrangement is very satisfactory, and gives excellent curves in both cases, as the strong light which falls on the outer waxed-paper is sufficiently moderated before reaching the argentic gelatino-bromide paper by passing through the waxed envelope.

The under curve is required in the case of the meteorological instruments, as duplicates have to be sent by this Observatory to the Meteorological Office of the Board of Trade; but, only wanting a single trace for the magnetograms, we adopt a different method in their case. The old waxed-paper process with strong lights answers very well; but we find that a large amount of gas can be saved by substituting the argentic gelatino-bromide paper and diminishing the lights. With lights low, and a narrow slit between light and paper, we find the curves sharp and the ground white. Blue glass has been tried in front of the slit without producing any apparent change in the curve.

The developing solution recommended by the firm is two ounces of saturated solution of oxalate of potash to half-an-ounce of saturated solution of protosulphate of iron and six minims of a sixty-grain solution of bromide of potassium. With this developer the barograms and thermograms are faint, but come out well when the bromide is omitted. The magnetograms, on the contrary, which are exposed directly to the gaslight, come out too quickly with the original developer; so we use ten minims of bromide instead of six, and the curves are perfectly under control. S. J. Perry.

Stonyhurst Observatory.

ALBUMEN AND GELATINE PLATES.

From a couple of articles which have recently appeared I notice that the Editors have been experimenting with albumen in connection with gelatine emulsion, in which direction I have myself worked, though not exactly on the same lines as the editorial experiments.

My object and intention in the introduction of albumen into the film was rather to secure certain mechanical or physical advantages than to emulate the fine quality of image attainable with the old collodio-albumen plate; and I think, so far as my experiments went, my mode of working is likely to bring about as full a degree of success as that given by the Editors.

My first experiments were made, with the object of preventing frilling, with a sample of gelatine otherwise so good that I scarcely liked to discard it on account of its one fault. The albumen was applied to the glass as a substratum, just as was formerly done in the case of collodion plates; but I found under these circumstances it had very little effect—at least of a beneficial character. I tried the simply dried and also the coagulated albumen substratum without much difference in result.

I next turned my attention to the application of an albumen solution to the gelatine film after it had thoroughly set. For this purpose I used a solution consisting of two parts of albumen to one of water, thoroughly beaten, and, in fact, treated in the manner usual in the preparation of albumen. Ammonia and acetic acid were both tried as additions for the purpose of facilitating the clarification of the albumen; but eventually I concluded to discard all such additions as being not only useless but actually injurious, inasmuch as they introduce some amount of uncertainty as regards sensitiveness. The plain albumen diluted with half its bulk of water was simply beaten, left to itself for some hours, then strained through cambric, and applied in the ordinary manner of a dry plate preservative.

In order to produce a marked result I found it necessary to submit the gelatine surface for a somewhat extended time to the action of the albumen. The film, being saturated with water, does not readily absorb the albumen; and if the plate be removed too soon from the solution a mere surface coating results, which is removed in the first washing of the plate previous to development. If, however, the plate be permitted to remain in the albumen for a period of about five minutes the "preservative" penetrates into the pores of the film by diffusion, and the result is a very considerable hardening of the surface.

If, after the plates have been dried—or even when but partially (or surface) dry—they are immersed in methylated alcohol the albumen is coagulated, and a still further hardening is the result. But there is a slight tendency to irregularity in this action, especially if the application of the albumen has been brief, and its penetration into the film not complete. It need not be feared that the hardening of the film by the coagulation of the albumen will render it impenetrable to the developer, as the alkalinity of the latter suffices by its solvent action to counteract any waterproofing effect that might be thus produced. I am speaking now solely of alkaline pyro., for I have never used ferrous oxalate with albumen plates.

The primary effect of such an application of albumen is to remove *almost* all chance of frilling from plates made with even the softest and most expensive of gelatines. I say "almost," because if in pushing an under-exposed plate a sufficient quantity of ammonia be used, or its application be sufficiently prolonged to remove the albumen, then the gelatine film is obviously left in much the same condition as it would have been in without any use of albumen. But even then I am inclined to think there is a less tendency to frill and blister than would have been the case without the albumen.

With regard to sensitiveness and other qualities I can say but little, having given no attention to that part of the subject. That the presence of the albumen brings about a difference in the colour of the developed image—a beneficial difference—is beyond dispute; but whether it affects the sensitiveness or the rapidity of development I am not prepared to say.

So far as the direct addition of albumen to the emulsion is concerned, I can scarcely see in what manner it can act differently from my mode of applying it to the film. In neither case is there any chemical action between the albumen and the silver salts, but merely a mechanical action, which can scarcely differ in effect whether the albumen be dissolved in the emulsion or diffused throughout the film by soaking. C. Beckett Lloyd.

ON CHOOSING A SIZE FOR *CARTE* AND CABINET NEGATIVES.

It is not always that one can choose a size for our *carte* and cabinet negatives. It is often done for us. Businesses are bought with all cameras, printing-frames, negative racks, &c., standing, or a favourable opportunity occurs in commencing business to purchase a lot of good apparatus, and the accustomed proportions are adhered to. Sometimes a size has been chosen to combine as many conveniences as possible—landscape and portraits; and as businesses have grown it has been found too inconvenient to change when the benefit to be obtained is, apparently, slight.

To all, however, who contemplate launching out in business for themselves, I would suggest the desirability of a very careful calculation of this question from all points of view before deciding upon the size to be adopted for the negatives they expect to take in largest number. Such a weighing of the subject involves many more considerations than at first might be thought likely. Not only is there cost and economy, general adaptability and suitability, convenience of working and convenience of storing, but it has to be considered how readily a damaged piece of apparatus can be replaced or the stock increased without delay when the requirements of business call for it.

My own experience dates from a period some years before the introduction of the *carte de visite*, when the stock sizes of the photographer were few—quarter, third, half, and whole plate being the dimensions then used, with stereoscopic and the large stereoscopic, or seven and a-quarter by four and a-half. I first used the quarter size, and afterwards regretted its adoption, as there was not sufficient margin in case of stains; I then changed to the large stereoscopic, and to that size doubled when it became customary to take several pictures on one plate and print from them all. These double stereo. plates I cut into two for convenience of storage, and to fit the large stock of printing-frames of the first-named size which the printing-room was provided with.

I found this a very handy size. It gave me a-quarter of an inch more margin at the top than did the quarter plate, and allowed full scope for adjustment if the sitter did not happen to be placed exactly in the middle of the plate, as often will happen, especially with children's portraits. As years rolled on and business grew I worked with my usual plates, rarely, if ever, giving further thought as to whether it was the most suitable. But upon the gradual introduction of gelatine plates into my dark room—I must confess to having been very conservative; I would not let go my hold upon collodion till I was quite sure of gelatine, and I have no reason to regret my slowness—as I began to run up large bills for dry plates, I reopened this old question. I found that by using for a double *carte* negative the old half plate—which, as my readers will remember, was six and a-half by four and three-quarters—I should save, at the prices then prevailing for the best plates, almost a penny upon each one used, and this, as I need not say, represented a very large sum at the end of twelve months. I estimated the saving would cover all the cost I should be put to if I made a change in my stock size.

This change would enable me to make another important alteration. For cabinet pictures I had a special arrangement, so as to take two on a large plate; I always have chosen to have plenty of margin on my negatives of all sizes, so as to be sure of clean pictures under every contingency, and for cabinet portraits I used 10×8 plates. Dry plates do not, as a matter of safety, require so much waste area—no oyster-shell markings, no comets, and no split films. I felt certain that a half-plate would answer all my requirements—would be cheaper, lighter, and occupy much less space in my negative-room, while with a sufficient number of dark slides there would be no need to use double plates; in fact, for any but very small sizes double plates are a mistake with gelatine, in my opinion.

I decided to use the same size of plate for *carte* and cabinets, and thus made a very great saving of cost and added greatly to the general convenience of working arrangements. One size of plate instead of two to keep in stock and one size of dark slide were only required. I may here state that I had my slides altered so as to take a half-plate either vertically or horizontally for *cartes* or cabinets, which led to another convenience. The double cabinet plate did not permit groups, or, indeed, any subject, to be taken lengthwise, while the single plate permits either one or the other indifferently to be used—an arrangement which, of itself, shows the inadvisability of the double plate, the actual usefulness of which is gone by now, seeing that plates can be piled at one's elbow in grosses, if necessary, ready sensitised.

I had every reason to be satisfied with making the change, but the most pressing necessity for alterations lay in the negative room. I preserve all my portrait negatives, and their ever-increasing number began to cause anxiety as to the stability of the floor and walls. Taking average photographic glass to be "21 oz.," it requires little calculation to show that it only needs seven or eight thousand negatives to weigh a ton, ordinary-built houses not being calculated to sustain many tons on one floor. This question was a very grave one, for I had heard of one photographer with a large stock of negatives stored in the upper part of the premises having to rebuild a portion through the walls giving way, the defect being discovered only just in time to avoid a great disaster. After careful weighing of the matter in all its bearings—the subject being one that could not with any convenience be reopened unless some radical change in processes took place—I arrived at a further decision about the working sizes of my *carte* negatives; and though from the remarkable falling off in the demand for *cartes*, owing to the preference given to cabinets, the subject of storage of *carte* negatives assumes a less prominent position, I propose in another number to describe how I rearranged *carte* sizes, both as to printing and storage.

G. Watmough Webster.

CAMERA PRINTING.

It may, perhaps, prove interesting to some readers of the Journal if I record a trial I have made of the system of producing transparencies by artificial light described in a leading article in last week's issue. I preface what I have to say by remarking that from the nature of my avocations it is frequently very inconvenient for me to practise this branch of photography during the daytime, and hence the great value to me of any system in which artificial light may be employed.

Following the general line of directions given, I have employed a pamphengos lantern of the usual four-wick class as the source of light. The condenser is formed of two plano-convex lenses mounted with their convex surfaces towards each other. Not having a large objective of the kind recommended in the article I made use of that belonging to the lantern, which is to all intents and purposes a portrait combination of quarter-plate dimensions, with this exception—that the back lens somewhat exceeds in diameter the front one.

The camera was fitted with a No. 1B *carte* lens, having an aperture of one inch and seven-eighths, with a back focus of four inches and an eighth, the equivalent focus being six and a-quarter inches. After various stops had been tried I selected one having an aperture of three-quarters of an inch as that to be utilised in all my future experiments. The process I employed was wet collodion, and the developer one containing fifteen grains of ferrous sulphate to the ounce of water.

Having interposed a plate of ground glass (the focussing-screen of a 10×8 camera) between the lantern and the negative, which was one of average density, I directed the light upon it with all the power of which four wicks are capable, obtaining a disc of about eight inches in diameter upon the ground glass. I then exposed the plate in the camera for thirty seconds, but this proved insufficient to bring out an image which was at all effective. Another plate was prepared and exposed for one minute. This afforded an image which in the centre was all that could be desired as regards vigour, but fell off very much towards the margin. Thinking this might be accidental another plate was exposed for the same time, a different sample of collodion being employed. Like the former this, too, showed a falling-off towards the edges, although the middle of the plate, for the space of about two inches across, was quite intense.

What was to be done? It was evident that the ground glass did not act the part of a perfect diffuser of such rays as fell upon it from a direction greatly differing from that in which it was desirable they should be transmitted. I was aware that the illumination would be more equalised if I interposed a second plate of ground glass in the manner directed; but, alas! I had no second plate in my house.

Recollecting that in an article in your last ALMANAC there was a suggestion for slightly deflecting rays of light under circumstances nearly similar to those existing in this case, I at once dismembered a large graphoscope and transferred the large lens, which exceeded six inches in diameter, from its place as the all-important factor in the mechanism of the "peep show" (as some one once designated a graphoscope) to a position close up to the ground glass, placing it on the lantern side at first, although subsequent experiment satisfied me that any special side was of little consequence. This immediately caused such a concentration of light upon the negative that not only was the previous weakness of the marginal illumination entirely overcome, but the *quantum* of light transmitted to the object-glass from the negative so great as to compel a shortening of the exposure in a most material degree. The transparency obtained by the aid of the graphoscope lens was simply perfect as regards equality of illumination, the extreme margin being quite equal to the centre in vigour.

I offer the above as an addendum to the suggestive article to which I have made reference. J. HOUSTON.

EXPERIENCES ON THE THAMES.*

FROM Shillingford the scenery becomes more flat, and, although we made one or two "shots" at Benson Village, we got nothing of interest until we reached Wallingford. Wallingford has the aspect of a well-to-do country town, and, like many another place of interest on the Thames, can boast of a "hoary antiquity." The Saxons, the Danes, and the Romans have each in their turn settled there. It was a borough in the days of Edward the Confessor, and there was a mint there before the Conquest. We learnt we might still see traces of the ruined old castle—the same castle which stood a deal of battering about by General Fairfax during the Civil War, and there learn how—

"Time's gradual touch
Has moulder'd into beauty many a tower,
Which, when it frown'd with all its battlements,
Was only terrible."

We did not make a detour to the castle, for we understood it would not form a suitable subject for the camera. It was also at Wallingford where Stephen besieged Matilda and finally arranged with her that he should reign for his lifetime, and that her son, afterwards Henry II., should succeed him. We had a few "shots" at the old churches of Wallingford, and also at the curious Town Hall ("Town 'all," the natives call it), the latter possessing no great attraction for the camera. However, it faithfully records how we kept those good rules we formulated before starting, for its clock-face marks ten minutes to ten o'clock. It was the first view we had taken that morning. By the river we got several pictures of the bridge with the church on the opposite side, and also of cattle along the banks, with distant Thames scenery.

Leaving Wallingford we next came to the village of Newnham-Murrell, with its old church and gabled belfry peeping out of a cluster of trees. A short distance further on we came to Mongewell, with a handsome country seat and beautifully-laid-out gardens; and then, after passing Cholsey, we came to the picturesque village of Moulsford, which lies close to the river. It has a pretty rustic church with a farm-house beside it, half hidden amongst luxuriant foliage. About the banks, on the Moulsford side, are many clumps of fine trees, through which we could catch glimpses of the distant downs above the village of Streatley, which we were nearing. We spent several plates in securing views of this prettily-situated village and antiquated church, which dates from the fourteenth century. Moulsford Ferry, a short distance lower down, was the next spot which afforded interest for our cameras.

Resuming our voyage and passing by South Stoke we arrived at Cleeve, with its picturesque overfall and lock. The best view of the latter is on the up side of it, with the Streatley Hills in the distance as a suitable background. There are many pretty "bits" about Cleeve, and especially around the old mill. We investigated, at some risk, the stream around the mill, often nearly getting into trouble through being too curious. However, we got a "shot" at that "antiquated structure," being probably the first photograph ever taken of it. These old mills, as a rule, form suitable subjects for the camera, and this would have been no exception had we had a wider-angle lens. We experienced considerable difficulty in selecting a spot to get this view; in fact, I had about given it up when I remarked to the Philosopher—"This is the spot we ought to take it from." "Then, why not?" he at once asked; and when I argued it would be rather difficult to pose the camera in a boat, and almost as difficult in the stream, he quietly asked me—"Why not the latter? It is but a question of depth and strength of current." We ascertained the depth and found it did not come much above the middle of the stand, and with care we could manage the current. I manipulated whilst the Philosopher poised himself so as to form a suitable balance on the other side of "our lugger." We obtained that view, and christened it the "Philosopher's bold idea!" We were charmed with the environs of Cleeve Mill and with the whole route from Cleeve as we came nearer those gently-rising hills above Streatley, at the base of which the twin villages of Streatley and Goring are situated, on either bank of the river—the former in Berkshire and the latter in Oxfordshire—and both joined by a wooden bridge, whence we could obtain one of the finest views of the river, with its silvery windings at length lost in the distant hilly ranges above and below. The river is wide here, and encloses a series of islands clothed with a bountiful supply of foliage. One view at Goring particularly charmed us, and that was its pretty church, which forms the subject of the first illustration. It is dedicated to St. Thomas à Becket, and is of Norman foundation, though the tower alone preserves

the peculiar features of that style. It stands close by the water's edge, and beside it is a graceful cottage. The whole is most picturesquely situated and surrounded with over-hanging foliage. We considered a picture of this church well repaid our visit to Goring. The houses at Goring reminded us very much of those at Clifton Hampden, and, with

* Concluded from page 424.

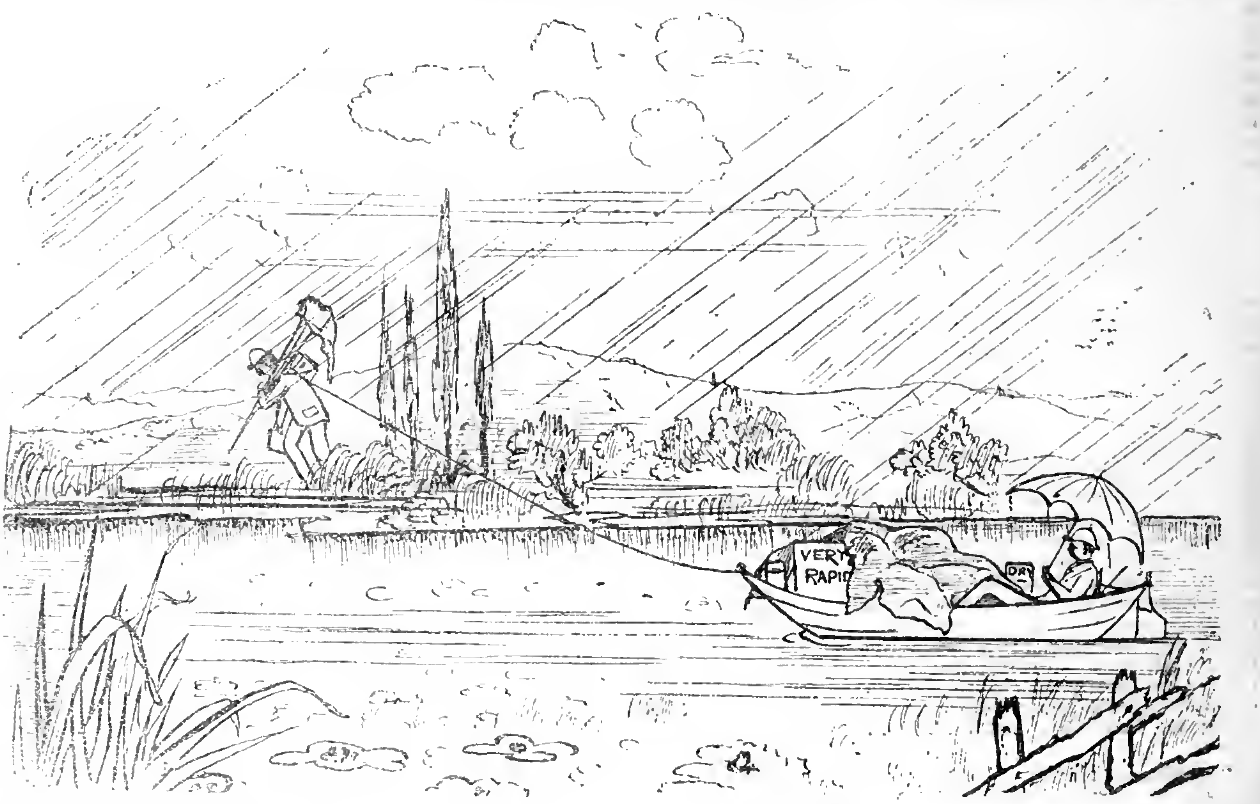
their trim and neat gardens and generally-comfortable look, they form an excellent example of the "peasant homes" of Old England.

The good people at Goring are somewhat unsophisticated and rural. We had occasion to visit one of their village inns—"hotels" they now call them. We inquired what we could have to satisfy our hungry cravings, and found that it was a choice between eggs or our being the innocent cause of the murder of a chicken and having him cooked, which would require time. We decided on the former alternative. Now, the Philosopher has a morbid horror of French eggs, and I can sympathise with him. The Philosopher at once asked—"Are they French?" (Mine host understood "fresh.") "Certainly," was the ready answer. We were a little annoyed and worried when on more carefully pronouncing the word "French" mine host understood, and at once rising to the occasion replied—"Why, sir, I'm surprised at your asking me such a question; I've never seen a French egg, and my eggs have 'growed' on the spot." We at once asked him to let us have a few of his "home-grown" eggs without further delay. We eventually made friends with that man and stayed at his "hotel" that night, and had no reason to complain of the somewhat rural treatment we received.

Pangbourne was another of those beautiful spots on the Thames we left with regret. Pangbourne has many attractions, and all around the neighbourhood there is much to interest the art-lover. The village, moreover, has a long history. It is mentioned in the *Domesday Book*. Its manor and church were afterwards given to the Abbot of Reading by Henry II., whilst later on it formed a part of the possessions of the Duke of Somerset, who was executed in 1553.

Continuing our route from Pangbourne, through Whitchurch lock, we meet with rather flat scenery on our right, with undulating chalk hills on our left. Then we reach Hardwicke House, which is beautifully situated amidst luxuriant foliage on the slope of a wooded hill rising from the river. Hardwicke House is a specimen of a manor house of the Tudor period—a large, gabled structure of red brick placed on a terrace of earth raised considerably above the river. Here Charles I. spent much of his time during the troublous period of the civil war; and Charles II. is also said to have made the mansion his hiding-place. Needless to say, Hardwicke House forms an interesting subject for the camera from the opposite bank.

Our next point of interest *en route* was at Mapledurham, with its old, mossy mill, church, and manor house, which for centuries has been, and



Streatley is also worthy of a visit, and next morning we obtained two or three photographs of this pretty village, with a background of gently-undulating hills, from the summits of which many magnificent views of the Thames can be obtained. The next view that occupied the camera was the "Grotto"—a prettily-situated mansion about half-a-mile or so farther down the river. The "Grotto" derives its name from at one time possessing a fine grotto, which does not at present exist. The mansion is prettily surrounded with handsome trees, and forms a suitable subject for the camera. Thence we hastened onwards until we reached the villages of Pangbourne and Whitchurch, which, like those of Goring and Streatley, are joined together by a bridge. The chief interest at Pangbourne centres in its weir and charming surroundings. Many interesting views may be obtained about here; the weir, rustic cottages, and overfall, with a background of wooded, rising slopes, all form subjects more or less suitable for the camera. Greville Fennel, in his book, *The Rail and Road*, gives the following description of Pangbourne:—"Pangbourne is another of those pearls of English landscape which our river threads; no sweeter spot is within many miles. The Thames seems especially fond of disporting itself here; and loth, indeed, to leave, it loiters in the great depth of the pools, creeps slyly under the banks, frolics as a kitten after its tail in the eddies, and then dashes hurriedly off beneath the far-stretching wooden bridge, as if to make up for time truantly lost." The village of Whitchurch is also interesting, and we obtained good views from the opposite bank of the church and mill peeping out of a mass of dense foliage.

still is, the seat of the Blount family. It is a fine combination of pointed gables, tall roofs, ornamented chimneys, and porches—a regular Elizabethan mansion in the richest style. We obtained good views on the up side, with the mill and church in the far distance, the monotony of the placid water being broken by the reflection of the fine trees on both sides of the river, which here is deep and broad, reminding us of those beautiful lines of the poet:—

> "Though deep, yet clear; though gentle, yet not dull;
> Strong without rage; without o'erflowing, full."

We had not sufficient time to do justice to Mapledurham, as we wished to hurry onwards; so, passing by the interesting village of Purley, we at length reached Caversham, where we left our boat, deciding to finish our course down to Windsor on another occasion. There were many reasons why we decided to give up, one chief reason being the shocking weather we had had, and the general uncertainty of results in consequence. A facetious friend sent us the above illustration as a silent and laconic explanation—"Why we came home."

J. J. Acworth, F.I.C., F.C.S.

IN THE LABORATORY.

To many it would seem as if gelatine plate treatment had been so exhaustively written upon that nothing more were left to be said on the subject. Are not excellent specimens by the now almost universally-used forms of treatment of the plate after exposure to be met with all over the land? True it is there are still two modes of development—the ammoniacal and the ferrous oxalate: but this last has now so very few votaries that it may be said to be fast dying out. To its celerity and energy mainly the ammonia owes its hold in the professional room. As to amateurs, they give it preference because of its, to them, scientific treatment. Many hold to scorn anything that is done in a simple and direct manner, so long as a more complicated mode of treatment exists. Now, the very opposite should be the thing—absolute simplicity combined with perfection of results. This will leave more time for something far more useful—the due consideration of the artistic aspect of photography.

In view of all this it may not be too bold to say that a reaction must take place in the manipulations the plate has to undergo after exposure. Ammoniacal development may in fact be made to yield to its more modern competitor—washing soda. I have no idea of who was its original introducer, but, whoever he was, he rendered a most signal service to photography. There is no substance in the laboratory more valuable than this simple and modest agent, and, probably because of its simplicity, it is readily pushed on one side to make room for inferior agents. And yet medical opinions have clearly proved ammoniacal fumes not only unsuitable but positively dangerous to some constitutions. Men with delicate organisations, after even a brief period in the dark room, under the influence of ammoniacal effluvia meet with sleeplessness, restlessness, nervousness, and irritation. They should no longer. Let them heed carefully what is to follow, and they may for ever after discard that baneful agent—ammonia.

It is not at all improbable they may think management in cases of over- or under-exposures an impossibility with soda. Let them discard this idea from their thoughts altogether. Soda is just as manageable as ammonia, and it may be asserted that the former will in many cases give passable results when the ammonia will prove utterly useless. I shall call the system I am now advocating

Modern Development:—

Formula for Winter.

Ordinary washing soda	5 ounces.
Bromide of potassium	15 grains.
Water	50 ounces.

Formula for Summer.

Ordinary washing soda	5 ounces.
Bromide of potassium	40 grains.
Water	50 ounces.

The simple difference between the two formulæ consists in an increase of the bromide of potassium in the winter formula on to that of the summer. In both spring and autumn twenty to twenty-five grains would suffice.

To each ounce of the above about one grain of dry pyro. is required, and it is only put in with the solution when about to develope. You then have energy to any amount.

In using large plates—as I never use any plate whatever but those I make, and as they are very repellent owing to the quantity of chrome alum they contain to counteract frilling—I make it a practice to first soak my plate a couple of minutes in water and then apply the developer. By that means uniform action is obtained, and no marks or marbling are encountered. Half-a-minute or so after the developer is on the plate the picture makes its appearance very faintly; it goes on slowly but steadily growing in density, and, if exposure be correct, in three to four minutes development is complete. The whole time it has been under absolute control, for the building up is one that can be most easily followed and stopped directly it is seen the picture has acquired the proper density. Of this last any amount can be got without the least trouble; if there be a danger, it is to get too great a density, and chalky pictures nowadays are rightly looked upon as worthless. But, supposing the negative somehow or other has got a little too dense, there is nothing easier than to bring it down to a suitable state. All you have in the world to do is to leave it in the fixing bath until the desired reduction has taken place; this may take half-an-hour, it may take an hour, or it may take several hours, but the desired end will be attained. There is nothing better yet than a twenty-five-per-cent. solution of hypo. as a fixing bath. Eight ounces of hypo. to thirty-two ounces of water make a fair quantity of solution and will last some time.

But if, on taking the plate out of the fixing bath and giving it a rinse to examine it, the picture prove rather thin, merely give it a slight additional rinse and lay the plate by. It will now, thus left, gain in density, the hypo. in the film and the oxygen of the air working together to bring about the desired end. How the reaction really takes place I would be at a loss to explain, and as the matter is only valuable to me in its actual bearings I do not intend to take further trouble about it. By the time the plate has acquired the desired opacity it will also have gained a yellow colour most unpleasant to many, but it will print splendidly. Of course the plate has to be thoroughly washed when it has once acquired the requisite density.

A great eyesore to some is the colour of a plate developed with soda. All the rubbish that can be urged on that score I have heard *ad nauseam*. Let the sensible man discard all such nonsense; the colour of the deposit of a soda-developed plate, left intact, is simply printing perfection and nothing short of it. Should it, however, occur that you have to retouch the negative, and are at a loss as to its value so as to be able to retouch adequately, here is the simplest of all means to bring the negative at once to the lead-pencil tone. Swill your plate with the following solution:—

Alum	3 ounces.
Water	20 „

The reaction is very rapid in this solution, and any yellow deposit will disappear with this alone. If alum be not at hand take and swill your plate with the following solution, which, by the way, is not mine:—

Sulphuric acid	1 drachm.
Water	20 ounces.

The effect with this is magical; but care must be taken that this solution remains but the briefest of time on the film, for it is also a great reducer. Moreover, a thorough washing of the negative is necessary to ensure its ultimate safety. This must be an answer to those who always urge colour, for lack of other objections, when speaking of the soda developer.

That the system now advocated is absolutely sound, and in every way satisfactory, I have sufficient proof of in the experience of a professional photographer to whom I communicated it, and who has now had it exclusively in use for the last twelve months. The results he obtains with it are second to none whatever. There is a rich vigour and bloom on his negatives I never saw surpassed even in the wet process, and the transparency of the shadows is of the very purest. This stands to reason, if one but consider the relative proportions of bromide used to the soda, and the character of this last. There is no abnormal reduction with this method of working; no shadows veiled from an inordinate quantity of the obnoxious ammonia, used, mayhap, on some make of plate that lacks the power to withstand this rough and over-severe treatment. You may hear that in summer there is a greater tendency to frilling with the use of the soda developer. This may be counteracted most easily by the mere addition of alum to it; no fear then of frilling, and a certain quality not to be despised will be imparted to the negative.

For ordinary studio work, where constant practice reduces exposure to a certainty, the above will be found all-sufficient; but for abnormal cases—such as happen not unfrequently when out of doors and under trying circumstances, when exposures are forcibly guess work, or when they suddenly have to be brought to a close because of unexpected movement in foliage or otherwise—means must be provided to counteract ill effects as far as possible, to partly make up for under-exposure, or accommodate cases of over-exposure. Of the two, under-exposure is by far the more trying, and, when very pronounced, it is not to be got over, work which way one may. When the case is not very bad, however, the use of an absolutely-saturated solution of soda without any bromide whatever, and an increase of pyro., will restore things or, at anyrate, make the most of them.

When presumable over-exposure has to be dealt with double the quantity of bromide should be used, or a drop or two of citric acid solution added to the normal developer. Should the picture, notwithstanding, come out too quickly the developer were best washed off, a new one taken with three or four drops of the citric acid solution (strength, ten per cent.)—and things would proceed satisfactorily. To those whose experience is limited it is astonishing how much may be done to overcome the ills attendant on incorrect exposures. What is most wanted in such cases is to keep perfectly cool and collected; meditate on the mishap, and well weigh the *pros* and *cons* of the case with all its bearings, and the chances are ten to one in favour of your mastering the difficulty. It has happened to me to forget to revolve the small stop after focussing, and to consequently have a much over-exposed picture. As it invariably strikes one after the thing is done I merely bore the fact in mind, and on getting home easily balanced things and made them work quite smoothly notwithstanding, save the slight want of sharpness attendant in such a case.

All this summarises what might be called a comparatively-new line of working, and one for which I venture to predict a steady spread and a bright future, which it well merits. All I will now add is—fairly try it.

A. F. Genlain.

Addendum.—Even in the professional laboratory it is advisable to always have at hand a bottle of well-saturated solution of soda when, by some means, exposure proves to have been rather short, as it is a ready remedy. In the same way for over-exposures: it is wise to have a bottle of a solution containing double the quantity of bromide (say):—Water, twenty ounces; soda, two ounces; bromide, thirty-five grains. A drachm or more of this last quickly added to the solution in the developing dish will at once retard development and make things work harmoniously.—A. F. G.

ON THE TREATMENT OF HUSNIK'S PHOTOLITHOGRAPHIC TRANSFER PAPER.

Dissolve one part of bichromate of potash in sixteen parts of water, and add four parts of alcohol. The solution is reddish yellow; add caustic ammonia until the colour turns light yellow. An excess of ammonia does no harm. This bath is poured into a shallow zinc vessel, into which the photolithographic paper is dipped with the prepared side up; after a few minutes it is taken out again and hung up to dry at an ordinary temperature, and in the dark.

When dry the paper is well burnished and exposed to sunlight for a few minutes, or in the shade for half-an-hour to an hour, under a negative in line or stipple. The paper is then coated with fatty printing ink, thinned with oil of turpentine until it is of the consistency of syrup, and rubbed with fine cotton wool until only a thin surface coating remains. After a few minutes, during which the oil of turpentine has evaporated, the print is laid in cold water and left to soak for half-an-hour before proceeding to develope with a soft sponge. The development proceeds by placing the paper on a firm, flat, smooth support and working the sponge with a circular motion, yet without too strong a pressure. The ink easily washes from the whites, but remains adherent to the lines of the drawing. The print is next washed in clean water, then dried first with blotting-paper, and afterwards hung up to become perfectly dry. The back of the paper is then moistened with a sponge, and pressed as usual upon the zinc plate or stone.

DETAILS OF SEPARATE OPERATIONS.

The Bichromate Bath.—This should keep and still answer its purpose. As is well known, our photolithographic transfer paper is prepared so that the fundamental film is insoluble in cold water, while the uppermost film is soluble in cold water. If one were to use a bichromate bath dissolved in water only the upper film would be dissolved off and float away in the bath. For this reason alcohol is added to the bath, which many theorists often seek to avoid because they would like to understand it better. In alcohol, also, the upper preparation of the paper is especially insoluble, and this addition alone hinders the complete washing away of the uppermost film.

The chrome salt bath may, indeed, work for some time well enough without the addition of caustic ammonia; but in a few weeks a reduction of the chromium salt into brown chromic acid and chrome oxide will take place, because the alcohol and the organic substances dissolved off from the paper while lying in the bath have a reducing action upon the chrome salt even in the dark, which makes it necessary to maintain the sensitiveness of the bichromate in the bath by neutralising it by the addition of caustic ammonia into monochromate of potassium and ammonia, for which an excess of ammonia should be present. Thus a neutral or alkaline chromate salt bath is perfectly durable, and also does not decompose when exposed to light (because all monochromate salts are insensitive to light) and it always works with certainty, which cannot be said of a bath subject to decomposition, as a decomposed bath itself acts more weakly; and the product of the decomposition—namely, tho chrome acid chrome oxide—has a tanning effect upon the gelatine of the paper, by which its development is partly or wholly affected.

It may be thought that a neutral chrome salt bath should render paper saturated with it insensitive to light; but it must be remembered that the bichromate was neutralised by a volatile base, namely, ammonia, which evaporates away completely during the drying of the paper and leaves behind it the original double salt—bichromate of potassium. Even if instead of this salt the double ammoniacal salt of chromium were originally used for the bath, its neutralisation would not in the slightest affect the sensitiveness to light of paper saturated in it; because the yellow crystals of monochromate of ammonia do not resist the action of the air, but lose one combining proportion of the ammonia, would be decomposed into reddish dust, and leave behind the bichromate of ammonia.

One may also observe a distinct change of colour in the paper which, before drying, is light yellow, but afterwards appears a reddish-yellow, and, therefore, latterly only contains bichromate.

The question as to which salt of chromium is best suited for the bath is easy to answer when one knows whether in asking the question most stress is laid upon the greatest sensitiveness to light or upon the price. If price be taken into account then bichromate of potassium is preferable; if sensitiveness is to decide the matter then monochromate of ammonia is to be recommended.

As I have already shown in my work on *Lichtdruck*, the chromate of ammonia is considerably more sensitive because all the chromic acid present in it may be decomposed by the light, since by the decomposition of one equivalent of the chromic acid monocarbonate of ammonia is formed, which, not being able to resist the influence of the atmosphere, loses part of its ammonia and leaves behind the sensitive double salt, which can again be reduced one-half by light, and so on until all the chromic acid is decomposed. When stable metallic salts are used only one equivalent of the chromic acid is decomposed, leaving behind the monochromate, which is then no longer reducible by light.

I myself prefer the potassic salt, as it is quite sensitive enough for what I want, or, at most, it may have to be replaced in the winter months of November, December, January, and February by the ammoniac salt; but only where there is a great deal of work to be done, and where it, therefore, seems advisable to accelerate the exposure.

It is best to have a zinc trough for a bath quite as large as the size of paper to be used (porcelain or other vessels may also be employed, but are neither so cheap nor so durable). The solution itself should be kept in stock in two bottles. The large one (which is the store bottle) should contain a solution of half a kilogramme of bichromate of potassium in seven and a-half litres of water, and should contain as much caustic ammonia as to make the solution appear yellowish and make it smell very slightly of ammonia after being shaken up. If there be already a slight excess of ammonia present one should take care not to add a great excess of caustic ammonia, as this corrosive base has the property of rendering the gelatine softer and depriving it of the power of setting. It may happen that in summer a bath rich in ammonia may soften the gelatine of the paper so much that when developing the gelatine shall loosen off, even in cold water. The gelatine, however, forms a protection to the paper from the rubbing of the sponge, and by the smoothness of its upper surface gives much sharper lines and dots than a merely albumenised paper would. But even if the softening of the gelatine should not have proceeded so far as to render it soluble in cold water, a far less degree of softening is very disagreeable and injurious in the various operations. For example: the paper after being transferred adheres tightly to the zinc plate, and cannot be removed from it without injury to the picture. J. HUSNIK.

ENGINEERING PHOTOGRAPHY.

[A communication to the Engineers' Club, St. Louis., U.S.A.]

IN discussing photography this evening I wish what I have to say to be taken rather as a progress report than as the dictum of an expert, which I certainly do not claim to be, my own knowledge of the subject having been gained chiefly during the last six months in the leisure moments I have had at my disposal, while actively engaged in my regular work. Having so recently passed through the primary department I suppose I can give good advice to the beginner.

The object which I have in view this evening is to give the principles on which the art depends, with some of the chief uses to which it can be applied, which, I hope, will be instructive or interesting to all; and, at the same time, to give such practical suggestions and formulæ as will be of value to anyone who desires to learn to take photographs.

My own knowledge on the subject has been got from books, experiments, and talks with other amateurs, having learned but little from the regular profession, who, to a greater or less extent, regard it as a secret trade, where all information should be paid for. A beginner would probably save time and money by taking a few lessons in a good photographic establishment. That you may understand the change brought about by the introduction of the gelatino-bromide dry plates, which have only been on the market for a few years, some statement of the principles on which photography depends is necessary.

No engineer who has been successively tanned and bleached by field and office work need be told of the power of the sun to greatly modify the colour of many substances. The salts of silver are those mostly used, being the only ones known to be capable of use in the camera, while the compounds of iron and chromium are extensively used in sun printing. Silver chloride, iodide, and bromide are the salts used, the action of light being nearly the same on each. If light is allowed to fall on the chloride under favourable conditions it is reduced to the subchloride. As is well known, it is the short vibrations of light which so synchronise with the vibrations of the molecules as to throw off one atom of chlorine, while the longer vibrations have no effect. The opposite of this occurs when light falls on the eye; so a photographer, by using blue glass and blue curtains, can admit most of the chemical rays into his studio while excluding much of the heat and blinding light, thus enabling his subject to keep cool and to have his eyes wide open. The chemical change is very slight in the silver salt, so that very little energy is necessary, the result depending solely on the vibrations being of the right length, just as the trotting dog may have thrown down a bridge which allowed a four-horse waggon to safely pass over it. Captain Abney states that chloride of silver may be heated to that point at which it will itself give off chemical rays without being decomposed. The action of light on silver chloride is as follows:—

$$2\ AgCl = Ag_2Cl + Cl.$$

This change takes place much more readily if some substance is present to absorb the chlorine. In the presence of moisture we have

$$4\ AgCl + H_2O = 2\ Ag_2Cl + HCl + HClO.$$

If silver iodide be used in the presence of free silver nitrate, as in the wet-plate process, we have—

$$12\ AgI + 6\ AgNO_3 + 3\ H_2O = 6\ Ag_2I + O + 6\ AgI + 6\ HNO_3.$$

The nitrate, being capable of absorbing the freed iodine, is called a sensitiser. If silver bromide had been used in the above reaction, on account of its greater sensitiveness to light, the following reaction takes place after exposure—

$$4\ Ag_2Br + 6\ HNO_3 = 4\ AgBr + 4\ AgNO_3 + N_2O_3 + 3\ H_2O,$$

which, with the aid of the nitrous acid set free, soon destroys the latent image. This accounts for the disappearance of the latent image in the so-called tannin dry plates when they are kept after exposure before developing.

With the gelatino-bromide plate the case is quite different. The gelatine acts as a sensitiser, absorbing the liberated bromine without setting free any injurious acid, so that such a plate will keep as well after as before exposure, which seems to be indefinitely, if properly made and not allowed to get too hot.

Some manufacturers claim that the plates, like whisky, improve with age. They probably become more sensitive on account of an increase in the size of the grains of bromide. This property of the gelatino-bromide plates, taken in connection with the fact that they are the most sensitive compound known, make them so superior to all others for engineering purposes that I do not consider it worth while to mention any others, referring you to books on the subject.

The Lens.

The lens is the most important thing in the outfit, and, while the character of this paper does not admit of a full discussion, a few remarks may not be out of place.

Makers should, and usually do, state in describing a lens the size of the objective, the equivalent focal length, and the size of the plate covered. Lenses are usually compounded to overcome spherical aberration and other obstacles to making a correct picture, and the equivalent focal length is the distance from the optical centre of a compound lens to the ground glass, when the rays striking the objective are parallel. The following equation gives the relation between the conjugate foci of a lens:—

$$\frac{1}{v} = \frac{1}{f} - \frac{1}{u}.$$

Where v is the distance from the optical centre to the image, u the distance to the object, and f the equivalent focal length, it is evident that if u is infinite $v = f$. If the image is to be $\frac{1}{n}$ the size of the object we have:—

$$\frac{1}{v} = \frac{1}{f} - \frac{1}{n\,v} \text{ or } v = \frac{f\,(n+1)}{n}.$$

The quickness of a lens depends on the size of the objective and the shortness of the equivalent focal length. If r be the radius of the lens and f the focal length then the time of exposure is given by the equation—

$$t = C\,\frac{r^2}{f},$$

where C is independent of the lens, depending on the value of the light and the quickness of the plates. By means of this equation the quickness of the different lenses can be readily compared.

The Camera Box.

The camera box which I have is made by Anthony, and is called "The Novel." I selected it after looking at all I could see in the St. Louis supply stores, and, taking its cheapness into consideration, it is probably as well suited to an engineer as any. The important points are that the plate can be used with its longest dimension either vertical or horizontal, that it can be turned about a horizontal axis so as to make the plane of the picture vertical when the camera is pointed up or down, and that the lens should be capable of being moved vertically.

The tripod should be light and portable, folding up so that it can be easily carried.

Dry-Plate Holders.

Of these there are a great variety; but by far the most convenient for an engineer are the paper holders, which add very little either in bulk or weight, making them suitable for field work. They are patented, not very well made, and sold high, because one cannot get along well without them.

Time of Exposure.

The question of how long to make the exposure is the most difficult one connected with photography, since it depends on so many things, such as the lens, the diaphragm, the quantity and quality of the light, and the colour of the object. The time varies from the instantaneous—when the object is white and in bright sunlight—to hours in enlarging or in photographing microscopic objects.

To give a beginner some idea: if he wish to photograph a landscape with a Darlot lens, medium size stop, and in bright sunlight, two seconds will suffice, while I have never succeeded in taking a portrait in an ordinary room with less than thirty seconds' exposure when no stop is used. A good way is to expose different parts of the same plate unequally, then notice which exposure gives the best result. The only way to learn is by experiment; and after spoiling many plates the learner will know by intuition how long to keep the cap off. A professional hardly ever looks at his watch, though a beginner should not only observe the time, but record it also.

D. C. Humphreys, C.E.

(To be concluded in our next.)

WHERE TO GO WITH THE CAMERA.

[It is hoped that this series of articles will be continued at regular and frequent intervals during the vacation months, and we shall be glad to receive contributions to the series from any friends able to treat of new and interesting ground.]

A FEW DAYS IN BOULOGNE AND AMIENS.

"Why don't you exhaust the beauties of your own country before going abroad to visit others?" is the question one sometimes hears asked; and, if all you want can be summed up in beautiful country scenery and familiar surroundings, then you may certainly do worse than stay at home and spend your holiday among leafy lanes and shady woods, chattering brooks and brawling rivers, or at some spot along the coast where you may divide the time between the enjoyments offered by land and sea. But what some of us frequently want is a complete change from our ordinary routine and usual habits, and this may be got by a continental trip of a very modest description, without going very far afield or making any great demands on either time or purse.

Crossing the "silver streak," on holiday thoughts intent, is an experience which happily falls to the lot of many amateur photographers, and the day I chose for it was one to rejoice the heart of anyone who could appreciate delightfully genial and warm weather, with just sufficient breeze to temper the seasonable heat. From Folkestone to Boulogne, on a glowing, sunshiny day in the middle of June, is a pleasant preparation for the holiday which the photographic "Syntax in search of the picturesque" may have in anticipation. About halfway across the channel we find ourselves in the middle of the competing yachts in the Cinque Ports Yacht Race from Dover to Boulogne, and very beautiful they look in all their glory of outspread canvas—a good chance to get a flying shot; however, I had taken none but slow plates of my own make, so that the opportunity must be lost.

Expecting no difficulty in getting my luggage through the Boulogne "Customs" my hopes were rudely shattered by one of the gentlemen gorgeously arrayed in all the dignity of uniform, who, passing several other passengers, quietly fastened on my packages and led me off in triumph to the inquisitors, or, to speak correctly, the officials, who for a consideration condescend to overhaul your belongings and generally turn them topsy-turvy. These gentlemen, with the perverseness of human nature in general and French human nature in particular, carefully overlooked all my packages except that one containing my precious plates, which they were particularly anxious to see. It was of no use explaining in the best French I could muster that the little brown paper parcels contained photographic plates, "sensitive to light," for in weight and shape they were too suspiciously like dynamite to be lightly passed over. "Messieurs" must *see* them, and as there was no help for it I had to undo one of the packets and spoil a few plates. Fortunately they were well packed in fours in orange paper, and, although several of the loose packets were handled in a bright light, I did not find upon development that any of them were fogged.

While some of the brethren of the camera go further afield for their pictures I thought I would see what there was within a few miles of Boulogne which would make pictures. Anyone who knows the town fairly well will remember the large cemetery on the St. Omer road. From the eastern and higher end a capital general view, with the cathedral in the distance, can be got, and one which well repays the expenditure of a pair of plates. Passing from the cemetery gate along the avenue of trees (known as "Des petits Arbres") under the ramparts one has a charming peep of the cathedral dome across the moat, with the citadel (in which you are told Napoleon III. was confined) for middle distance. This requires to be taken in the afternoon, when the light is so placed as to bring into relief the roundness of the circular stonework. By the way, enthusiastic amateurs who desire this picture must beware of the ubiquitous gendarme; for, though the Boulogne fortifications are of the medieval description, the consequences might be unpleasant if he were inclined to be "cantankerous." A little lower down is the Porte Gayole—a picturesque old gateway, and making a very characteristic picture. Let us go through and we shall find ourselves in the "Haute Ville," where, from the end of the Rue de Lille, one gets a very attractive street view typical of French town architecture. The ramparts enclosing the old town contain a series of pictures for the eye to feast on, but not, alas! for the camera, the distances being too great. One or two plates are, however, exposed on quaint "bits" of old-world building, which force themselves into notice.

Leaving Boulogne itself, the little fishing village of Le Portel affords abundance of opportunities to the photographer in search of the picturesque. The quaint fisher dwellings with their appurtenances—nets and sundry other gear—would give material for an unlimited number of pictures.

But, after all, a day or two at Boulogne will be all that a casual visitor will care for. In my own case, after being there a few days, I began to look around for the most promising place in which to spend the few more days which would terminate my holiday for 1884. It occurred to me that I had heard something of Amiens as a photographable town, so to Amiens I started; and I may say at once that from the point of view of an amateur who wishes to spend three or four days picture-making I cannot conceive a more enjoyable town. Pictures positively force themselves on one, the difficulty being not what to take, but what *not* to take. Here we have a town of 60,000 inhabitants full of busy life, containing in its midst a magnificent gothic cathedral, and passing through the most picturesque part of it a river which sometime in the middle ages was built over and about in such a way that it is made to form a sort of network of canals, over which are innumerable bridges of stone and of wood of all shapes and of all sizes. From these points of vantage one gets an infinite variety of glimpses of quaint, old, gabled houses perfectly mirrored in the placid water beneath, and odd-looking, flat-bottomed boats like something between a gondola and a fishing punt, the said boats being among the most useful, as they are certainly most characteristic, objects of the town. Go to the banks of the Somme on a market day and you will see for what purpose they are used. Piled up with vegetables and fruit of all kinds they are so evidently part of the furniture of the place that one begins to wonder how it is that we in England have no use for them. Useful as is the river Somme to the picture-maker, the natives find in it literally their means of subsistence. Many of the mills in the manufacturing portion of the town are worked by water power, and one has only to wander about by the banks to see what a large number of the leisure hours of the Amienois are devoted to the mystery and art of angling. There you may see them of all ages, sizes, and classes, and at all hours, doing their utmost to lure the finny tribe to destruction. Very handy in the foregrounds are these gentle anglers. They come in very appropriately, and, from the exigencies of their craft, make the best of sitters; neither do they raise their eyes from the important occupation of watching the float to stare point blank at the camera.

The great feature of Amiens is its grand cathedral, which, seen from almost all points, towers far above all other buildings—a veritable giant of architecture. No fear of losing your way in Amiens, as you have only to take the bearings of your "diggings" in relation to the giant, and when you are at a loss steer for it. The magnificent west front at about 3.30 on a bright summer afternoon is a sight to rejoice anyone who can appreciate the richness of detail and harmony of design displayed by the old builders in this superb poem in stone. Every niche with its statue, every grinning gargoyle and grotesque head, is thrown into relief and endowed with a beauty which nothing but direct sunlight can give. The interior of the edifice is in keeping with the expectations raised by the view of the outside front. Entering at the great west door and looking from end to end of the building one beholds a sight always full of significance as being in keeping with its solemn uses. One of the greatest treasures of the cathedral is the well-known statuette, *The Weeping Angel*—a charming little work, apparently not more than two feet in height, and placed somewhat too high for its great merit. Placing ourselves under the care of the sacristan's son, a smart little lad, we proceed to explore the towers and upper portion of the cathedral, ascending countless steps, and finding ourselves at last just over the great west door, and behind some colossal statues. Now we pass along the outside of the lower portion of the roof under the flying buttresses. What a view of the fair town at our feet! What glimpses between the buttresses, suggesting gigantic photographs in Brobdignagian frames! Inside the building, again, what a picture from one transept to the other!—both adorned with beautiful rose windows of gloriously stained glass. Then over the roof itself, where our young friend slyly opens a trap door and bids us look down, "quarante-quatre mètres" below, where we see sundry insects crawling about, said insects turning out to be human beings viewed "end on" from above.

Photographs of the cathedral are, of course, to be obtained by purchase, and some of them are very good. All the views of the west front, however, give a false idea of the place, owing to the short-focus lenses necessarily employed in their production. They show the south tower taller than the north, which is just the opposite of the fact; so we content ourselves with producing a picture including a moderate angle, and leave the more ambitious to "Messieurs" the shopkeepers. A fair idea of the vastness and great height of the cathedral may be got in the view from the north end of the Pont du Don, as from that point there is a greater sense of proportion in the relative heights of the great building and those of the surrounding houses. It is difficult to photograph, however, as the light, except in the early morning, is dead against the camera.

The day on which I left Amiens was Saturday and a market day, with plenty of chances for groups of market women, &c. That sort of thing, however, requires rapid plates; and as I am one of the "slow" men I exposed my last films on the less ambitious but equally-picturesque subjects by the river side which I have attempted to describe.

J. J. Hollway.

FOREIGN NOTES AND NEWS.

A Photographic Method of Producing a Lithographic or Zinc Plate Printing Plate in High Relief.—Dr. Kayser's New Changing-Box, Dark Slide, and Dry Plates on a Flexible, Transparent Support.

Herren Benecke and Fischer, of St. Louis, and Herr Frank, of Frankfort-on-Main, have patented a process for obtaining relief plates for printing in relief in a photographic manner, regarding which, the *Correspondenz* says, we see here a practical application of a long-known fact, and especially of the researches of Rottier and Waldack, in which* the influence, first, of the concentration of a solution of ferrous sulphate; secondly, of the acids added to the developer; and, thirdly, of the influence of different iron salts upon the result of the development process, were discussed. The patentees have confined themselves to utilising the results which can be obtained by varying the concentration of the developer; yet the specification speaks of the preparation of a small positive transparency and of a subsequent enlargement as the real part of their discovery. [The *Correspondenz* then takes the opportunity of remarking on the irregular manner in which the specifications are issued from the Patent Office, and the consequent inconvenience arising from not being able to arrange them, or to have them bound in order, and the difficulty of referring to them. It seems that, though this patent is numbered 26,242, the patent office had not yet published the specification of No. 26,222, which was granted on the same day!]

"The process is intended for the production in the photographic manner of a picture the outline and shadows of which shall be formed of small dots placed more or less closely together, and for the transference of this picture by etching upon a zinc or other plate and of rendering it suitable for multiplication by high relief. The production of the picture is done by first taking from a negative in the ordinary photographic manner as small a transparency as possible. The latter is then enlarged, and thus a picture is produced that consists of a great number of small dots, and which, when transferred by etching upon a zinc or other plate, is suitable for giving off a print in relief. In the preparation of pictures suitable for this purpose it is necessary that the collodion which is employed for the preparation of the transparency should be as thin as possible and but slightly iodised, as that affects the size and the distance between the dots which compose the picture. By using a stronger or weaker developer it is in one's power to give the plate a finer or coarser grain. The following proportions are suitable for the production of the small transparency:—Alcohol, 30 grammes; ether, 30 grammes; guncotton, 0·8 gramme; iodide of ammonium, 0·8 gramme. To develope the picture a fluid of the following composition is most suitable:—Water, 480 grammes; ferrous sulphate, 30 grammes; acetic acid, 60 grammes; alcohol, 30 grammes. By using a stronger solution a coarser, and by using a weaker solution a finer, grain is obtained; thus it can be made coarse or fine at pleasure. Also the impression from the enlarged negative may be transferred to stone in any known way, and then the picture multiplied by lithography."

In the *Mittheilungen* Dr. Kayser gives an account of his unbreakable transparent substitutes for glass as a substratum for negatives, and of his substitute for the changing-box. These have already been referred to in our columns, though not fully described. The drawbacks accompanying the use of gelatine dry plates for landscape photography are—1, their weight; 2, the amount of space they occupy; 3, their fragility; and, 4, the danger of their being spoilt by damp. The most usual substitute for glass is a paper support, which is rendered transparent either before or after the production of the picture. Dr. Kayser has adopted as his support a mixture of collodion and gelatine, which, he says, fulfils all the requirements of transparency, firmness, and unbreakableness, and is very easily made. The plates can be made of any desired thickness, from one millimetre to a-quarter of a millimetre, and of any desired size. Although, generally speaking, they are unsuitable for very large sizes—say not much above twenty by thirty centimetres—yet he has produced films thirty centimetres wide by two metres long. The picture may be taken upon the film in two ways:—The film may either be placed on rollers in a dark slide, as Mr. Warnerke does; or it may be cut to the size of a plate, and during the exposure be pressed back against a glass plate in the dark slide. Dr. Kayser has chosen the latter mode, and finds that when properly focussed the pictures are quite sharp, although the sensitive film is behind a sheet of glass. In order to be able to change these substitute plates easily, when on a journey, Dr. Kayser has constructed a particular dark slide with sleeves (which he has also patented), so that the changing of the plate takes place in the dark slide itself. For use in this dark slide each film is loosely fixed with wafers into a piece of black cardboard, by which the necessary stiffness is imparted to the film, and, at the same time, the light is prevented from penetrating to the films behind that which is being exposed. The manner of working is that, after each exposure, the operator inserts his hand into the light-tight sleeve, and, drawing the exposed plate and its accompanying piece of card out into the sleeve, places it in the dark slide again behind all the other films. A dark slide of this sort some six centimetres in thickness is said to hold easily fifty films loosely mounted upon the pieces of black cardboard, and with films of eighteen by twenty-four centimetres the whole hardly weighs two kilogrammes—say in round numbers less than four pounds. The manner in which these films fulfil the requirements already enumerated Dr. Kayser gives as follows:—1. *Lightness.*—Each 18 : 24 c.m. plate on cardboard weighs fifteen to twenty grammes. 2. *Space.*—Fifty films without cardboard form a thickness of about a centimetre and a-half; with cardboard backing three centimetres. 3. *Liability to Break* is completely done away with. 4. *Greater Keeping Qualities.*—On long

* *Bulletin de l'Association Belge de Photographie* vol 1., p. 119.

journeys, where hundreds of plates have been carried, each set of fifty or one hundred plates may be soldered into a thin tin case, and are thus perfectly protected from the influence of moisture, air, and dust. It is also a real advantage in the photographic printing process that, owing to their thinness, the plates may be printed from either side.

RECENT PATENTS.

APPLICATIONS FOR PATENTS.

No. 10,226.—"Apparatus for Dissolving and Changing Pictures in the Magic Lantern." B. J. Edwards, The Grove, Hackney.—*Dated July* 16, 1884 (complete).

No. 10,680.—"Gelatine Plates for Use in Photography, Manufacturing and Using the Same." A. J. Boult; communicated by G. Eastman and W. H. Walker, gentlemen, both of Rochester, Munroe, New York.—*Dated July* 28, 1884.

Production of Photographic Negatives for Photolithography, Photozincography, &c. By Alexander Borland.

(This invention received provisional protection only.)

My invention has for its object the production of photographic negatives having suitable transparent lines, dots, or stipple, so that such negatives may be used in the processes of photography, photozincography, photo-engraving, photo-etching, or phototype productions, such negatives being either portraits, views of buildings, machinery, or landscapes or other objects.

Hitherto the means employed in making such negatives has been to take a paper photograph and stipple the same by hand, or by impressing the same with any rough substance, such as sand-paper, glass-cloth, or muslin made hard by steeping in glue, or by fine wire gauze, and, after being so impressed, filling the indentations with some kind of soft and dark pigment and then making a negative of the same.

In my process I obtain a like result by placing a screen of wire or hair gauze, or perforated metal, or paper, or other substance having suitable perforations, or by means of a screen of muslin, net, or crape, or other suitable fabric, in front of the sensitive plate inside the camera, and then exposing to the object to be photographed in the usual way.

The screen may be placed as nearly as possible in close contact with the sensitive plate, or at a distance therefrom if a modified result is desired.

Where a reverse of any of the above kinds of grain or texture is required I expose a sensitive plate with the wire or other screen to a uniform white surface, the pattern negative so produced being used instead of the wire or other screen; or a pattern negative may be made by photographing a grain or pattern that has been drawn on white paper.

The wire or other screen or pattern negative may and can be used either in the process of photographing paper prints or in photographing the objects themselves, as before stated.

Our Editorial Table.

Messinesi's Changing-Box.

We have been shown an ingenious improvement or extension of the principle of the well-known automatic changing-box introduced some years ago by Mr. George Hare, the novelty consisting in the use of inner boxes, by means of which relays of fresh plates can be introduced when the first dozen have been exposed. In outward appearance the changing-box is precisely similar to the ordinary Hare's changing-box; but this shell is unprovided with grooves, the interior being perfectly plain. The plate-box proper, which contains the grooves, slides accurately into the outer casing, and when in position the simple withdrawal of a flexible shutter similar in character to that in connection with the sliding jaws of the outer box, opens the communication with the dark slide. After exposure of the plates this shutter is re-closed and the films are perfectly protected from light. There is, further, an ingenious arrangement by which plates of smaller sizes can be used in the same slide.

As a matter of course, the dimensions of the box are larger in proportion to the size of plate than is the case under ordinary circumstances; but the difference is not great, a box for half-plates being about the size of the ordinary $7\frac{1}{2} \times 5$ apparatus.

We believe the instrument is not yet fully ready for the market. When it is we recommend an inspection of the arrangement, which, by means of one or more comparatively inexpensive inner boxes, renders the travelling photographer totally independent of a dark room.

Redding's Improved Pocket Ruby Lantern.

London: J. Robinson and Sons, 172, Regent-street.

This is an exceedingly convenient and portable lantern for travelling purposes, folding flat and fitting into a sliding case, which may be comfortably carried in the coat pocket. The body of the lantern is composed of coloured fabric, which renders it at once light and unbreakable. The top and bottom are of japanned tin, each being provided with a "cut off" which, while permitting the free ingress of air and egress of the products of combustion, effectually prevent the escape of actinic light. The source of illumination may be any ordinary night light; but a special light, made in tin boxes, is recommended by the manufacturers as possessing certain advantages over other forms.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on the 24th ult., the chair was occupied by Mr. J. H. Hare.

Mr. A. Cowan showed a cutter for making circles such as those in diaphragms, when these were made of card or ebonite. The cutter was made from a pair of steel compasses, the legs of which had been forged into bow-like form, and one finished with a point for centering, the other with a cutting point.

Mr. H. S. Starnes exhibited a camera for operating with small-sized plates, without carrying separate dark slides or changing-box. The bottom of the camera contained two wells—one for plates before, and the other for plates after, exposure. At the back was an opening through which the focussing-screen could be examined, and a sleeve of black cloth allowed the hand to enter and place the plate in position.

Mr. J. B. B. Wellington showed a plate from a portion of which green fog had been removed with a weak solution of ferridcyanide and hypo., similar to Mr. Farmer's reducer, but much weaker. The amount of ferridcyanide found sufficient for the purpose was four grains in ten ounces of hypo. solution, and when employed at this strength no perceptible reduction of the intensity of the negative had taken place during the time necessary to get rid of the green fog.

Mr. W. Cobb thought that green fog was an improvement to any negative, and that it was a pity to remove it. He (Mr. Cobb) then mentioned having recently had an experience of fogging with a dark slide having a revolving shutter. He had satisfied himself that this fogging was not due to light, but to some emanation from the leather of the revolving door. He had remedied it by coating the leather with a solution of thymol in alcohol, and exposing it for some days to the air.

Mr. Cowan said that there had lately been some correspondence on the subject; and as recently as the preceding evening, he had seen plates upon which insensitive marks had appeared where they had been nearly in contact with American cloth.

The Chairman remarked that it was a matter of great importance to camera makers, who now generally used leather for the hinges of dark slides.

Mr. W. Coles inquired whether the leather referred to by Mr. Cobb was black.

Mr. Cobb replied that it was.

Mr. Cowan said that black mixed with an oil medium would cause fogging, but not when used with a spirit medium.

Mr. Coles said that asphalte black had sufficed to produce complete fogging.

Mr. J. Barker mentioned a curious experience that he had had recently. A plate had been developed in the evening, but, as after a quarter of an hour no image appeared, it was stood up on a shelf as useless. In the morning, however, the image was found to have become developed.

Mr. J. J. Briginshaw had met with a similar occurrence.

Mr. Ashman showed some prints upon opal coated with citro-chloride of silver, and gave the following formula, differing slightly from one previously given:—

A.

Nelson's No. 1 gelatine	60 grains.
Water	$1\frac{1}{2}$ ounce.

B.

Chloride of sodium	40 grains.
Citrate of potash	40 "
Water	1 ounce.

C.

Nitrate of silver	150 grains.
Water	1 ounce.

B is added to A and the temperature raised to 150° Fahr. C, also at a heat of 150°, is then slowly added. Boil for ten minutes, allow to cool down to 150°, then add 100 grains of Heinrich's gelatine previously soaked in two ounces of water, and stir till dissolved. After setting and washing add one ounce of alcohol in which one grain of salicylic acid had been dissolved.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

On Saturday last, the 26th ultimo, the annual outdoor meeting of the above Society took place at Hampstead Heath. Owing to the unpropitious state of the weather throughout the day cameras, on this occasion, were "conspicuous by their absence." The weather, no doubt, also prevented a much larger gathering, as long before the hour of meeting it had settled down to a steady downpour of rain, compelling those who came early in the afternoon on purpose to enjoy the beauties of the Heath to seek shelter at the rendezvous—the Bull and Bush Hotel.

Here a substantial tea had been provided. The chair was occupied by Mr. William Ackland, the vice-chair being filled by Mr. William Brooks; about a dozen members were present. After tea the remainder of the evening was pleasantly spent under the influence of the fragrant weed, when some capital jokes were cracked and many amusing anecdotes related.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The sixth outdoor meeting of the above Society took place on Saturday, the 26th ultimo, Speke Hall and its vicinity having been fixed upon as the rendezvous for the day. The party was timed to leave London-road Station at 10.20 a.m., arriving at Speke at 12.45.

Considering that special arrangements had been made, and permission obtained to visit Speke Hall as well as the park and grounds of Hale Hall, it was surprising how few members had given in their names to the leader prior to the date of the excursion. Had the weather been fine it would no doubt have proved one of the most attractive meetings of the present season; but, notwithstanding the adverse conditions, the few members who took part in it had no reason to regret it, but felt themselves well repaid for the temporary inconvenience which they encountered.

Speke Hall is one of the most beautiful and perfect specimens of the domestic style of architecture peculiar to the Elizabethan period. The present building occupies the site of a much older foundation, and was the work of one Edward Norreys, who commemorates the fact by an inscription over the principal gateway:—"This worke, 25 yards long, was wolly built by Edw. N. Esq., anno 1598." A broad moat once surrounded the house, but this has long been superseded by well-kept greensward, out of which, except where crossed by the bridge, the Hall seems to rise like a rock out of the sea. The situation is charming, and the surroundings are highly picturesque.

From one side a noble avenue of tree leads down to the estuary of the Mersey, which is here at its broadest; and its proximity doubtless contributes to the luxuriant growth of the trees and shrubs, which would otherwise suffer from their vicinity to Widnes and kindred places, the emanations from which are so inimical to the surrounding vegetation.

A remarkable feature presents itself in the construction of the Hall, consisting of an interior court in which two fine old yew trees grow, much older than the building itself, and it is evident that the architect in the arrangement of his ground plan has been guided by the wish to preserve these trees. Unfortunately it was too cloudy for the members to attempt much in this part of the building; but the external faces of the Hall offered plenty of scope, and many were the points of view from which the members could obtain excellent results, of which they were by no means slow in availing themselves. Had the weather been brighter some excellent studies of foliage would have been secured.

To Miss Watt, the present owner of the mansion, the members were indebted for the privilege of access to the Hall and grounds. The rest of the programme was unavoidably curtailed by the weather, which compelled the party, after a fruitless attempt to reach Hale, to hasten back to Speke station for the return journey.

A wish was unanimously expressed that this visit should be repeated under more favourable conditions at some future day, coupled with the hope that the members of the Society generally would avail themselves more freely of opportunities of this kind to visit places which are interesting in so many ways, and to which access can be gained only by special permission.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

This Society met on the 20th June, Professor H. W. Vogel in the chair.

The Chairman presented the guest of the evening, Mr. Kilburn, of Littleton (New Hampshire), who had at different times sent interesting collections of stereographs to the Society. Mr. Kilburn is at present engaged in taking stereoscopic views of Europe and particularly of Germany, which command a ready sale in America amongst the Germans who have settled there. In the course of the week he had been in Berlin, and had already exposed 200 plates. He (the Chairman) then laid upon the table Dr. Schnaus's *Photographic Lexicon* and Dr. Eder's *Instantaneous Photography*, presented by the authors. The circular of the Photographic Society of Ireland, inviting exhibits, was then read.

Herr Rudolf, of Darmstadt, said a case had been brought against him in the law courts for imitating a work of art, in so far that he photographed a monument in a churchyard and sold copies of it. He contended that a churchyard was a public place, and he had a right to photograph it and all the monuments it contained. The complainant contended that it was an infringement of his copyright, and that a churchyard was not a public place. The court decided in his (Herr Rudolf's) favour.

Dr. Ehrmann, of New York, wrote to say that Notman, of Boston, and not Falk, of New York, had taken the first group upon the stage of a theatre by electric light, when, in 1881, in Sander's Theatre, Boston, he photographed several groups in the representation of the tragedy of Œdipus the tyrant, by a Brush light of 6,000 candle power, with a Dallmeyer's A 3 portrait lens, a No. 3 stop, and an exposure of twenty seconds.

A very interesting letter was next read from Herr Schoene, of San Francisco, in which he described another way of photographing in a theatre by electric light. Herr Schoene sent a number of instantaneous views, mostly marine pieces.

Dr. Kayser showed a number of landscapes taken at San Remo with his sleeved changing-box. This time he did not use films, but glass plates, and changed them while the sun was shining brightly upon the apparatus; yet there was no trace of fog on the plates. The glass plates were packed flat upon each other, and only separated by a sheet of black paper. Both negatives and proofs were unretouched.

Mr. Kilburn exhibited a very simple plate-box for dry plates. It simply consists of a box the length and breadth of the plates to be packed. Inside, across the bottom, two long white cords are laid so that the greater part of their length lies outside the box. The plates are laid down one by one, and the cords passed across the end of each one before the next one is laid down, and so on until the box is full.

The Chairman showed some new samples of his sensitive-to-colour process, namely—1. A colour scale photographed upon eosine-collodion, eosine-gelatine emulsion, and azaline-gelatine emulsion, from which it appeared that eosine worked better in collodion than in gelatine emulsion, while the azaline-gelatine emulsion did better than either. The second exhibit was two reproductions, thirty c.m., of Herr Menzel's newest and celebrated picture of the *Market Place at Verona*—one taken with an ordinary gelatine plate, the other on azaline-gelatine. In the former plate the white lights were light and unmodulated and the shadows pitchy black and without detail. Some parts of the picture did not come out at all, but formed broad, flat surfaces; other parts, such as the blue of the sky and the distance, appeared much over-exposed. In the photograph upon the plate stained with azaline the lights had the proper tone and were full of gradations, while the shadows were also properly graduated and full of detail. The place of the black spots in the first was taken in the second by well-exposed heads; the sharpness and purity left nothing to be desired.

The meeting was concluded with a description, by the Chairman, of the part of the new building of the Technical High School at Charlottenburg devoted to photography.

Correspondence.

THE ETHOXO LIGHT AND GAS EXPLOSIONS.

To the Editors.

Gentlemen,—In a letter, in your issue of the 25th inst., from Mr. Ives, of Philadelphia, the writer seems to insinuate that it has been said that the ethoxo light was *popular* in the United States at the time he took out the patent in that country for it. Your remarks (and it is to these that I think Mr. Ives refers) were, as far as memory serves me, to the effect that shortly after my publication in The British Journal of Photography of the generation of ethoxo gas a patent was taken out in the United States for a similar purpose.

I grant that he may not have seen or heard of it before he took out his specification, but still it always looks suspicious when a patent is taken out directly after the process has been made public in another country. If his discovery of the use of ether antedates the year 1879, and can prove it, then I willingly give him the credit of priority of invention. I worked it in public in the autumn of that year, and have continued to use it without a single failure ever since.

That Mr. Ives's generator is not altogether free from liability to explode is apparent from the directions given (if this should occur) in the catalogue published by the manufacturers of the apparatus; and this has occurred in more cases than one, if I am rightly informed.

My first apparatus was made on the saturator principle, but not with caps on the end to blow off, as I prevented this by a better plan, namely, the pumice chamber, and with which the Rev. T. F. Hardwich has recently made exhaustive trials, proving its undoubted efficiency to arrest flame.

Whilst upon the subject of lime light I may say that, in my opinion, cylinders will eventually supersede gas bags, particularly when we have them under a less pressure of gas with automatic gas regulators to regulate the flow and pressure. This, I believe, has been accomplished and will ere long be a marketable commodity. Whether we shall be able to purchase oxygen by the pound remains to be seen. Recent experiments seem to prove it possible; but the probabilities as to cost at present are against it.—I am, yours, &c., W. Broughton.

Eccles, Manchester, July 26, 1884.

"FREE LANCE" AND THE CILIARY MUSCLES.

To the Editors.

Gentlemen,—I think my meaning as to the contraction of the pupil of the eye by the ciliary muscles was quite clear. As far as I can see, the only word "Free Lance" could take exception to was the word "muscles." Strictly speaking there are no ciliary muscles at all, but there *is* a ciliary *ligament*. Strictly speaking the words I ought to have used should have been "ciliary *processes*." I chose to use the words "ciliary muscles" to make my meaning clear to persons who might not be so well up in the definitions of anatomical science as is "Free Lance."

In Erasmus Wilson's *Anatomists' Vade Mecum* will be found the following passage:—"The iris is composed of two layers—an anterior or *muscular*, consisting of *radiating* fibres which converge from the circumference towards the centre, having the power of dilating the pupil; and a *circular*, which surround the pupil like a sphincter, and by their action produce contraction of the area." Now this layer is connected by its periphery with the ciliary *ligament;* and, being muscular in its character, I took the liberty of naming it—being the apparatus for opening or contracting the pupil of the eye—the "ciliary muscles."

With all respect for "Free Lance," I venture to differ from him as to the rapidity of the action of these muscular fibres. Anyone who has seen a cat basking in the sunlight, and lazily blinking her eyes, will have noticed how comparatively slowly the pupil is contracted to a mere slit when the eye is opened. Again: if, standing before a window with a mirror in your hand, you alternately throw light and shadow into your eyes, the contraction and expansion of the pupils can be readily seen. These facts lead me to believe that the muscles of the ciliary processes do not act with great rapidity, but rather the contrary.—I am, yours, &c.,

July 28, 1884. J. R. Sawyer.

THE SOCIETIES' REPORTS.

To the Editors.

Gentlemen,—Mr. Herbert B. Berkeley, in your last issue, professes to "dispose of the word 'misrepresentation'" with which he had taxed me and other writers, yourselves included. He goes on to ask—"If a man writes that which is not the case does he not '*misrepresent*'—not wilfully it may be?" Of course the answer is obvious, that he does; but, to give relevancy to the question, he should have supplied some instance of my writing "that which is not the case," and this he has omitted to do.

Mr. Berkeley further put it that I have no right to object to being accused of misrepresentation, because I had stated that I had been misrepresented in certain reports in the Society's *Journal*, and says that I am thus "hoist with my own petard." What has this to do with it? I have given instances, and am prepared to furnish any further details, if required, fully bearing out my complaint. Mr. Berkeley, when called upon to point out any misrepresentation on my part, omits to do so, for the simple reason, as I am now entitled to submit, that none exist in what I have written.

Mr. Berkeley says that I am incorrigible—"even more incorrigible than Mr. Pringle." I will not in turn descend to personalities and the use of epithets, but will leave the reader to supply the one appropriate to the conduct of a writer who brings a charge of misrepresentation, and, when challenged to point out wherein it consists or withdraw the charge, does neither.—I am, yours, &c., W. E. Debenham.

July 28, 1884.

A CURIOUS PHENOMENON.

To the Editors.

Gentlemen,—A few nights ago I was developing a negative when the light in the dark room was very dull. After I had developed and alumed the plate I noticed that the developing tray I had been using was strongly luminous. On closer examination it was found that some developer still remained in the tray, and the addition of a few drops of the alum bath had caused the phosphorescence.

Being rather struck by the circumstances, I tried the effect of adding a strong solution of citric acid and alum to some of the used developer, and found the phosphorescence much more strongly marked.—I am, yours, &c.,

Salisbury, July 25, 1884. Nemo.

P.S.—The developer mentioned above was the ordinary pyro. without sulphite (Wratten's formula), and the alum bath contained a little citric acid.—N.

THE PHOTOGRAPHIC SOCIETY: ITS REPORTS AND THE PHOTOGRAPHIC PRESS.

To the Editors.

Gentlemen,—I do not intend to enter into the discussion between Mr. H. B. Berkeley and your other correspondents, but to make a suggestion that, I think, will remove several of the evils which he points out; and that is, let the Photographic Society of Great Britain appoint someone to report *what is actually said* by the various speakers, and his reports be sent to the photographic journals. Then let the editors, or someone whom they appoint (who has not taken part in the discussion), condense the report for publication; and the committee of the Parent Society might appoint someone to condense the report for their journal.

If the person who reports the various meetings but seldom takes part in the discussions, he has time to condense the arguments of the various speakers as the meeting goes on, and the report is perhaps as satisfactory as one can be. But if he be one of the principal speakers he is unable to put down what he *says* himself, and, when others are speaking, his thoughts are probably so centered on what he is going to say in reply that he is often unable to catch the whole force of their argument, and his report is, in consequence (I do not mean to say for one moment wilfully), not quite satisfactory to the other speakers or to the readers of the journals.

I am convinced that the gentlemen who report the meetings for the journals are far too high-minded to wilfully misreport anyone; all I contend is that it is impossible for anyone to correctly report a meeting in which he is one of the principal speakers. He is not doing justice to either himself or his report, because if he give the whole of his attention to reporting what is said he cannot think how to arrange his arguments in reply, and both himself and his hearers suffer in consequence—they because they lose the benefit of his knowledge, as he has not had time to think of the whole of the points bearing on the subject.—I am, yours, &c., An On-Looker.

July 29, 1884.

Notes and Queries.

Novice says:—"Will some kind reader inform me the remedy for the following:—After I have sensitised my albumen paper I find that all the gloss is gone and my prints are spoilt. My silver bath is sixty-five grains to the ounce of water, and I have only added a few drops of a saturated solution of carbonate of soda to neutralise any free acid."

Rev. P. B. says:—"I am about to take a photographic trip in North Wales. Can you offer any suggestion concerning apparatus?"——In reply: Seeing that there are so many attractive waterfalls and ravines in Wales, it will be well for our correspondent to have his camera and stand so adapted to each other as to enable him to place the plate in either a vertical or horizontal position. The camera stand, too, should be rather taller than is frequently the case.

G. A. writes:—"If I register a retouching desk which I manufacture can I take proceedings against anyone who copies my design? If so, please let me know the cost of registering."——We reply: A retouching desk is what is designated in patent phraseology "a configuration of parts," and is not a subject for registration, but for patenting. No registration that could be effected would prove of any utility in preventing imitation. The obvious course open to our correspondent is to patent his invention, and he must take this step previous to issuing any specimens of his invention by way of sale or otherwise.

"Is there any work or article published on the subject of microphotography as applied to the transmission of messages in pellicular form by the agency of carrier pigeons?—J. B. H."——In reply: One pamphlet, at least, was devoted to this subject soon after the close of the Franco-German War; but we cannot at present give particulars of its publication beyond this—that the name of M. Dagron was connected with it. It is probable that in a chapter in Tissandier's *History and Handbook of Photography* (published by Sampson Low and Co.), on "Microscopic Researches During the Siege of Paris," all the information required will be found.

In reply to "Amateur," who wishes to know why a sample of varnish made with methylated alcohol dissolves the collodion film from his negatives, whereas one prepared with the same ingredients (sandarac and seed lac) dissolved in common non-methylated spirits of wine has not the same effect, we would remark that, first of all, it is possible that in the former varnish the methylated alcohol may be much stronger than the other, and the stronger the alcohol the more likely is it to dissolve the collodion film. But, secondly, as methylic alcohol (wood naphtha) is in itself a solvent of pyroxyline, and as methylated spirits of wine contains a certain proportion of this naphtha, it is not difficult to account for the solvent action of one class of varnish as contrasted with the other.

Argol says:—"Will you kindly inform me as to the following:—If you wanted to copy a silver print which would you prefer—to make the negative with a gelatine plate or with collodion? If with collodion, is there a collodion manufactured especially for copying, or would ordinary negative portrait collodion do? Of course I wish to get all the fine gradations that the best gelatine negative will give, and the best results in every respect. Also, would you tone the print from which such negative is made with the acetate bath, or tone it black with the lime bath?"——In reply: If the special brand of plates with which we happened to be working at the time gave results of an unexceptionable character we would make use of one of them for the purpose mentioned; but, if these were in any way defective, then we would employ ordinary good negative collodion, such as that adapted for portraiture. We should not be at all particular how the print was toned, provided the details were well made out.

F. S. (Somerset House) wishes to know if there are ready and inexpensive means by which an intense degree of cold can be produced.——We reply: Not knowing what is meant in this query by an "*intense* degree of cold," a reply of a somewhat indefinite character must be given. For example: if our correspondent desires to cool a fluid or anything else down to the freezing-point of water, crushed ice will effect the desired end. If, however, to crushed ice common salt be added in the proportion of one part to two parts of the ice, and both be well mixed together, a degree of cold will then be produced exceeding by 35° Fahr. that obtained by the ice alone, or a few degrees below zero. But a still further descent of twenty degrees below the cold produced by the ice and salt may be secured by mixing nitrate of ammonia with the chloride of sodium, which is to be stirred up among the particles of crushed ice. The proportions suitable may be stated as five parts each of the sodium and ammonium salts with twelve parts of the ice.

"I have heard of the reproduction of negatives by a single operation, by which I mean that the first impression obtained is not a positive or transparency, but a negative. Is there any reality in this? and, if there be, will you afford a clue as to how it is done? It will greatly oblige,—Abies."——We reply: There are two methods by which a negative may be reproduced by a single operation. One of these is as follows:—Direct the lens of a camera containing a bromised collodion plate to the negative to be reproduced, and develope the image thus impressed by alkaline pyro. This ought to give a strong positive. Now, without fixing, apply diluted nitric acid (equal parts of acid and water) to the surface, by means of which the image will be removed, leaving the unaltered bromide still in the film. Wash, expose to light for a few seconds, and re-apply the alkaline developer, by which the bromide will be reduced, the result this time being a negative. A second method consists in an application of the dusting-on process, several formulæ for which are given in our Almanac.

AMERICUS inquires—"What are the names of American photographic newspapers, and rates of advertising for (say) twenty words?"——In reply: No list of American photographic journals has been published; hence we cannot reply to the querist. Let him communicate with the publisher of this Journal, stating precisely what he wishes.

Exchange Column.

No charge is made for inserting these announcements; but in no case do we insert any article merely OFFERED FOR SALE, *that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a* NOM DE PLUME *be thought desirable), otherwise the notice will not appear.*

I will exchange some new 12 × 10 and 15 × 12 plate carriers, in case, for some good photographs of English actresses.—Address, L. W. GREEN, 25, Marsland-road, Walworth, London.

Wanted to exchange a whole-plate Lerebours and Secretan lens, in good condition, for a quick-acting *carte* lens by any good maker.—Address, F. WHEELER, 18, Commercial-road, Hereford.

I will exchange a gem camera, twelve lenses, one quarter-plate lens, and a cabinet burnisher, all or any, for an 8 × 5 rectilinear.—Address, H. R. C. NAISMITH, photographer, 345, New City-road, Glasgow.

I will exchange Ross's No. 2A extra-rapid *carte* lens for Dallmeyer's No. 2B or offers. Also, camera, by Fallowfield, for two cards on $7\frac{1}{4} \times 4\frac{1}{2}$ plate; offers in accessories.—Address, C. ROWBOTHAM, Burton, Westmoreland.

I will exchange a Dallmeyer's No. 2B patent and a Ross's whole-plate universal lens, both perfect, for a Dallmeyer's No. 2A or Ross's No. 3 cabinet lens; mutual approval.—Address, W. DAKIN, Holly Bank, Nether Edge, Sheffield.

I will exchange a biunial lantern, dissolving tap, bag, boards, about 150 slides, &c., everything complete, light waggon to carry the above. What offers in good view apparatus to value of £20? Also a first-class cabinet lens, gem camera, lens, &c.—Address, 283, ABBEYDALE-ROAD, Sheffield.

I will exchange a gem camera, four lenses, repeating-back, good as new, 10 ounces each of silver bath and collodion, bottle of varnish, quantity of ferrotype plates, envelopes and preservers, also student's microscope, for backgrounds (exterior) or anything useful in photography.—Address, J. BOWLER, Jun., Oxford-street, Oakengates, Salop.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPHS REGISTERED.—

William Pankhurst Marsh, Norfolk Cottage, Bognor.—*Photographs of Fish Lane and Sands, Aldwick, near Bognor,* also *Bersted Church.*

William Rochard, Sea View Terrace, Bagillt, North Wales.—*Photograph of Interior of St. Winifred's Church.*

John George Gibson, The "Priory," Higher Grade School, Tynemouth. —*Photograph of Boat, "A Centenarian."*

Thomas Ball, 7, Clarendon-place, Kidderminster.—*Photograph of Old Locomotive Built in 1827.*

NOTICE.—*Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a* NOM DE PLUME *as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.*

NOTICE TO SECRETARIES OF SOCIETIES.—It is earnestly requested that when proofs of reports and papers read at the meetings of societies are forwarded to the Secretary they may be returned at once to our printing office, 43, Harrington Street, Liverpool, so that any corrections may be made before the report or paper is published. Last week but one we received at the moment of going to press a proof of a paper which had appeared in our previous issue, and which bore a very large number of corrections (many of them of a trivial character), all due to the copyist of the original MS.—not one to the printer. We are at all times anxious to do our best to secure correctness; but when the proofs are sent out and not returned we are bound to assume that the original MS.—especially when plainly written as in this case—is accepted as accurate.

RECEIVED.—Herbert S. Starnes; W. H. Harrison. In our next.

W. A. WEBSTER (Waltham, U.S.A.).—No further details were given than those published in the Journal.

STEEL ENGRAVING.—See an article on the subject by Mr. Wm. Brooks on page 244 of our volume for 1882.

Z. A.—Make the bichromate solution still colder by the addition of a little ice. All will then go well, we have little doubt.

W. W.—Not so good as the old-fashioned method. You should bear in mind that novelty does not always ensure excellence.

AMATEUR OPTICIAN.—The stops, as you suggest, would be better between the lenses than in front. The alteration *is* certainly worth making.

LOTUS.—Certainly make the silver bath decidedly alkaline before exposing it to the light. It is much better to expose the solution in a flat dish than in a bottle, as then the ether and alcohol with which it is contaminated can better be evaporated.

N. SIMMONS.—Under the circumstances you were certainly justified in refusing a re-sitting; but whether you were wise in doing so is questionable from a business point of view. Bear in mind that giving offence to a sitter often entails loss of business.

S. B. J. (Ceylon).—If the sample of gelatine be a really good one there is no necessity, in practice, of clarifying it with white of egg for enamelling silver prints; but if you use an opaque kind, or some of the commoner qualities, a decided advantage will accrue by your so doing.

W. B. C.—Do not discard the bath used for sensitising albumen plates because it has "gone black." All you have to do is to shake it up with a little kaolin and filter, when it will be rendered as good as new. The solution being even somewhat strongly discoloured will not injure its working properties.

A. B.—As your studio is situated we can scarcely recommend you to glaze it with ground glass. The white muslin curtains, or blinds, will enable you to soften the light sufficiently during the short working period the sun is shining upon it. Except when the sun is shining on the studio ground glass might possibly prove a disadvantage.

A. C. YOUNGHUSBAND.—If the hyposulphite of soda show a decidedly acid reaction to test paper you should not employ it for fixing paper prints, as it certainly shows it is an inferior sample. True, you may neutralise the acid; but, on the whole, you had better discard it altogether, and so be on the safe side. Good and reliable hyposulphite of soda is surely cheap enough.

GIAGGIOLO.—The specks in the enclosed portion of film are not such as we judged them to be from your previous description. They appear to us to be the result of some foreign matter—probably insoluble lime salts in the emulsion. If you make your emulsion with *hard* water—especially if you employ any form of ammonia emulsification—this is likely to occur from precipitation of the lime by the ammonia.

S. DEWDNEY.—If the bath worked well before it was filtered and fogged badly afterwards it is a fair assumption that the filtering-paper was the cause of the injury. As two different solutions behave in the same way, we think the matter is conclusive. Ordinary blotting-paper, although it is usually a good filtering medium, cannot be relied upon for chemical purity. You had better procure some good filtering-paper from your photographic chemist.

GALLOWAY C. MORRIS (Philadelphia).—The method of locally reducing the density of gelatine negatives by abrasion is by no means new in this country; it was described three or four years back by Mr. Barber, of Sheffield, who recommended cuttle-fish powder. Pumice powder is also used for the purpose; indeed, any abrasive material will answer. We do not think any advantage will accrue from the employment of either rouge or emery over those other substances mentioned.

W. G. GARCIA.—The cause of the flatness—want of rotundity in your portrait—is that you have used by far too much front light, and the retouching you have so elaborately done has only made matters worse. The untouched negatives certainly have yielded the roundest prints. It is difficult, without knowing the kind of studio you work in, to give you advice. However, stop off all the direct front light you are now using, and illuminate the sitter from the side, softening the shadows, if necessary, with the aid of a reflector.

J. J. H.—1. If the defects are not caused by dust, and, as you say, are not connected with the subsequent treatment of the plate, they can only arise from the presence of some foreign matter in the emulsion. Your data are, however, insufficient to enable us even to make a guess at the precise cause. See reply to "Giaggiolo."—2. Read what we said a few weeks back on the subject of iodide in rapid emulsions.—3. Alum is the more convenient eliminator, while *eau de javelle* is the more theoretically perfect. The strength of the former is not very material.—4. If the substance be really chloride of calcium it should not behave in the manner you describe. Drying by the method you have adopted should "restore" it perfectly.—5. We fear you will find some difficulty in securing a reducer that will behave as you wish. *The* difficulty with all reducers is that the tendency is quite in the opposite direction.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 6th inst., the subject will be the adjourned discussion *On the Effect of Coloured Media on Silver Prints.* On Bank Holiday an outing has been arranged to Watford. Meeting at Watford Station at 10.47; train leaves Euston at 10.15. Afterwards at the Essex Arms.

No. 1266. Vol. XXXI.—AUGUST 8, 1884.

ALBUMEN IN GELATINE EMULSIONS.

Reverting to this subject, we commence with a few remarks on Mr. C. Beckett Lloyd's communication in our last issue. That gentleman, we think, is labouring under a slight misapprehension in imagining that the application of albumen to the surface of the film will have the same effect as mixing it with the emulsion. In the latter case there can be no doubt whatever as to the presence of albumen in every portion of the film; but in the former, we think, it is extremely doubtful whether it is present in any but the very smallest traces, except on the surface.

Albumen, it should be borne in mind, is a colloid substance, and will not, therefore, readily penetrate such a film as one of gelatine. With collodion the matter is altogether different, the spongy and porous character of the film permitting the albumen to penetrate easily—not, however, by diffusion, but by mechanically filling the pores and interstices. By such an application of albumen to a perfectly-washed sensitive collodion film we secure merely the mechanical advantages sought to be gained by its addition to gelatine emulsion.

Some of our earliest experiments with albumen were made by soaking the shredded emulsion, after the removal of the salts, in solutions of albumen of various degrees of concentration, but the results were not satisfactory. The slight effect produced was due, in all probability, to the small quantity of albumen left clinging to the shreds of "pellicle," and not to any absorption—the same, in fact, as in Mr. Beckett Lloyd's case. The fact that he found five minutes' immersion to produce a result where shorter time did not will not in the slightest degree affect this argument.

Albumen, like all viscous solutions, takes time to mix thoroughly with water; and if, therefore, applied to a *wet* gelatine plate a certain period must elapse before the surface water is completely replaced by albumen. If removed from the solution before that point is reached then the film carries away with it a proportionately more dilute coating of albumen. If the application be made to a *dry* film a similar result accrues in the end. The absorption of water by the gelatine film from the albumen solution produces a concentration of the latter, or, at least, of the layer in immediate contact with the plate; and the increase of viscosity thus brought about causes a larger quantity of albumen to remain adherent to the film. Naturally, the longer the gelatine is permitted to soak (up to a certain period) the further will this concentration be carried, and thus the cumulative effect of prolonged soaking can be accounted for.

As to the value of a mere surface application of albumen to a gelatine plate: we cannot see that any great advantage is obtainable that is not more readily secured by other means. In the case of collodion, as we have pointed out, the conditions are altogether different, the albumen there penetrating into the film and conferring special benefits which we imagine to be altogether absent in the case of a gelatine film. In the latter instance—supposing, as we do, that the layer of albumen is completely external to the surface of the film—it is merely dissolved off by the developer, and any alteration in the character or quality of the image is in all probability due solely to its presence in the developer, and might more easily be produced by adding albumen to the developer instead of applying it to the film.

Many of the older dry-plate workers will be familiar with what has been written in past years on the subject of modifying the alkaline developer by the addition of apparently neutral or inert substances, with the object of securing variations in the colour of the image. Mr. William Brooks was the first, we believe, to put the matter in practical form, by his recommendation to employ acetate of soda and similar salts as additions to the developer in order to obtain pleasing tones for transparencies. Later the same gentleman, and more recently again Dr. R. L. Maddox, have recommended albumen for the specific purpose of modifying and improving the character of the image. Sugar and a variety of other substances have been used; indeed, practically, any addition—organic or inorganic—which can be made to the developer without interfering with its action will produce some special modification in the character of the developed image.

These considerations lead us to the conclusion that Mr. Beckett Lloyd is under a misapprehension as to the value of his application of albumen—which, by the way, is infinitely more tedious and troublesome than the plan of mixing the substance with the emulsion as we suggested. That a difference—probably an improvement in the character of the image—may be the result we shall not for one moment contest; but such difference or improvement, we contend, could be as effectually and far more easily secured by simply adding the albumen to the developer. One advantage Mr. Lloyd's plan would have over the albumen developer would be in the protective action of the albumen film when plates have to be kept; but here again our own plan possesses the advantage that the whole film is impregnated with the protective medium—not merely covered by a thin varnish.

It is in this thorough impregnation of the film with albumen that its chief advantages of a physical or mechanical character rest, while its chemical advantages, if any, cannot at anyrate be less than in Mr. Lloyd's plan. For hardening the film, for preventing its frilling and blistering, for rendering it permeable to the developer, it is absolutely necessary that the albumen should pervade its whole thickness; and, if we turn to the alleged advantages of that substance as a "bromine-absolver," it is obvious that it must be in contact with each individual particle of silver bromide. If, on the other hand, the question be narrowed down to the action of albumen as an adjunct to development, its action when diffused throughout the mass can, at least, be no less uniform and no less complete than when applied to the surface, while far less trouble is involved. In fact, so far as concerns the attainment of any physical benefits that albumen may confer, we think the plan we have already described is the simplest and, so far as we can yet see, the best to adopt.

We had intended touching upon the other portion of the albumen question—namely, its chemica presence in the form of silver albumenate, in the emulsion—but our remarks have already run out to the limit of our space. Since we wrote last we have entered upon a series of experiments, which lead us to hope that the problem of the introduction of albumenate of silver into an emulsion is not an insoluble one; but for the present we are not in a position to lay anything definite before our readers.

GRAIN OR STIPPLE IN PHOTO-MECHANICAL PROCESSES.

Perhaps in no one branch of photography has so much ingenuity been displayed as in the production of an ink-holding grain, or stipple, in connection with the different photo-mechanical printing processes. It is well known, that in all photo-mechanical processes in half-tones, in fatty ink, it is necessary to break up the different tints of the negative into a grain or stipple, more or less fine as the case may be; and various indeed have been the devices for accomplishing this end. As early as 1852 Talbot, in one of his patents, claims the use of fine gauze or net for the purpose. Since then it is surprising the amount of ingenuity that has been expended in "ringing the changes" on this and analogous methods, and the number of patents which have been taken out at different times in connection with this object.

Grain, or stipple, may be described as of two classes—one produced by mechanical means, and the other chemically. Amongst the former may be classed the variety of methods of utilising gauze net, or similar plans. The method employed by Talbot, in his etching process, was that of dusting the picture over with a resinous powder; and that of Goupil of combining gritty matter with the tissues with which the relief is made. There is also the process of Waterhouse, in which the grain is obtained by dusting over with a gritty powder a wet carbon print. Amongst the chemical methods we have that of Pretsch, in which the grain is produced in the film of gelatine; the collotype, in which the gelatine film is, so to speak, puckered up—a kind of reticulation; also the method of Messrs. Sprague and Co., of which we have presented our readers so many fine examples during the last year or two. In this process a grain is produced, very similar to that of the collotype, except that it is larger—more resembling reticulation in a carbon print. It would occupy far too much space even to briefly notice the numerous modifications for producing grain in either class, our present object being to direct attention to a plan which, so far as we recollect of what has been done before, possesses a certain degree of novelty. Whether in practice it will prove of much value remains to be seen.

In *Foreign Notes and News*, in our last issue, we gave a translation from the *Correspondenz* of a patent for securing a grain in a negative. The patent, however, is, as patents frequently are, very vaguely worded; but, so far as we can gather, the method is based upon utilising the granularity of the silver forming the image for producing the printing grain. The process appears to be this:—From a negative a transparency is made "as small as possible." This is then enlarged and a picture obtained, which "consists of a great number of small dots." Then follows a formula for the collodion and developer to be used.

Now, it is tolerably well known, in the collodion process, that the developer employed to bring out the picture has a marked influence on the size of the particles of silver which form the image. If we use pyrogallic acid we have them very fine indeed, and by using gallic acid we can get them finer still; indeed, it is quite possible to produce the particles so fine that the image partakes more of the character of a stain or dye than an actual deposit. But if iron be employed to develope the picture, then we get the image much coarser; and the more iron and the less restraining acid there are in the developer the coarser will be the particles.

On this fact is based the method of Herren Benecke and Fischer. They propose to produce from the negative a very small transparency, the image of which is composed of large particles of silver. Then when this image is again enlarged the particles will become very apparent, and so they claim to produce a grained or stippled negative suitable for producing prints with a grained surface. We have no details as to the degree of reduction necessary to obtain a useful grain, except that the transparency must be made as small as possible. From this, and what we know of the character of the particles composing an iron-developed image or collodion, we assume that microscopic proportions are meant. Now, it appears to us that if the reduction be so very great—for it must be in order to get a decided grain in the enlarged negative—and the particles of silver composing the image are large, when the picture is amplified much of the fine detail of the photograph will necessarily be sacrificed, however sharply it may be focussed in the enlargement. The patentees mention only collodion, but it appears to us that a much better result might well be expected to accrue if the gelatine process be employed in preference—at least for making the small transparency.

It is well known that emulsion may be prepared to yield an image with almost any degree of coarseness. Now, if the plate upon which the transparency is made be prepared with an emulsion in which the particles of bromide are coarse, the same degree of reduction will not be required as in the case of collodion in order to obtain the same degree of granularity when it is enlarged. That is to say, a comparatively large gelatine transparency, when enlarged to a given size, will yield a negative with as coarse a stipple as will be obtained when a very small collodion one is used. Hence we may expect from the former to obtain a negative the details of which, while the stipple is as coarse, will be much finer. We all know that an iron-developed collodion image, in which the particles of silver are far from fine, may be enlarged a dozen diameters or more without their becoming apparent. Not so, however, with gelatine; for, if the emulsion be coarse—as it usually is with highly-sensitive plates—it is often impossible to enlarge the image four or five diameters without the particles becoming painfully conspicuous.

An objection may possibly be raised to the stipple obtained from gelatine plates, which is that the grain will not be so even and regular as with collodion. This may be so, but we imagine the advantage of being able to use a transparency of moderate instead of microscopical dimensions to enlarge from will more than compensate for this, by the greater sharpness and crispness which will be secured in the resulting picture.

THE ECONOMIC PRODUCTION OF COLD.

It is unnecessary here to dwell upon the advantages to photographers and others of being able to obtain a degree of cold in any fluid or solid substance rivalling that produced by the agency of ice. We are all aware that ice, whether produced naturally or artificially, is the frigorific agent with which photography must ever remain economically associated. So temperate, however, is our English climate that ice is here a luxury—not a necessity; and it is only in the larger towns or cities, and not always in those, that it can be procured by purchase. The opportunities for its being obtained by those residing at a distance from such centres are, consequently, extremely limited, and this will continue so until the manufacturers of ice-making machines realise the fact that in the production of those of a small, low-priced class, suitable for domestic use, lies a great and lucrative future.

In the "machinery in motion," or western, gallery of the Health Exhibition there is a stall, presided over by a young lady, who invites the attention of the visitor to certain small machines for the almost immediate manufacture of ices. To this attendant we, in the course of conversation, started the difficulty of blocks of ice being an initiatory and continuous factor in the production of the ices. This was not a necessity, she said, as the firm which she represented supplied a freezing crystal or powder which, when placed in the machine and mixed with water, answered a similar purpose to ice in lowering the temperature.

The readers of The British Journal of Photography are well aware that by the solution of certain crystalline bodies a considerable degree of cold is produced. Hyposulphite of soda, for example—which we cite as a salt with which all photographers are familiar—when dissolved in water reduces the temperature to a very material extent. To give point to what we say we have in an ordinary four-ounce graduate placed water a little below the temperature of the atmosphere, the thermometer at the time of making the experiment registering 69° Fahr. On being immersed in the water the thermometer fell two degrees, denoting a water temperature of 67° Fahr. Upon throwing in a handful of crushed hyposulphite of soda the thermometer rapidly sunk to 44° Fahr., at which it remained for some time, indicating a reduction of the heat to the extent of 23° Fahr. as the result of this simple action. Having removed the thermometer and washed the bulb we immersed it in a second graduate containing water as before, and found that the degree of temperature indicated on the stem was 67° Fahr., as in the previous instance. This fact noted, we next took up a small handful of crushed nitrate of ammonia, the reputation of which as a cold-producing agent is well known, and scarcely was it in until its potency was recognised and shown by the thermometer, the mercury having made a rapid descent until it reached 27° Fahr., or five degrees below the freezing point of water, representing a reduction of the temperature of the water to the extent of forty degrees.

Here, therefore, is a gain of a tangible character. If it be inquired at what cost it has been obtained, we reply "at no cost whatever," the first expenditure incurred in obtaining the salt being relegated to one side at present; for, upon decanting the solution of the ammonium nitrate into a metallic tray and exposing it to heat—that from the sun sufficing—the water evaporates, leaving the crystals hard and dry, and in readiness to be again dissolved and produce cold as before; and this may be repeated times without number. Here, therefore, by an initiatory expenditure of a small sum, we have always at hand an enduring means by which we can invariably ensure the production of a degree of cold below the freezing-point; and this without any cost of labour or appliances, if we except the means which we shall now describe, and which we have adopted on account of the ease and small cost of production, not being insensible to the fact that there may, although at present unknown to us, be other and better means for effecting the same end.

In a circular wooden vessel of any required dimensions is fixed a coil of tin gaspipe of large diameter, made in form like the worm of a still. In bending this in a sharp turn it will be apt to "kink," but this may be prevented by previously filling the tube with sand, after which it is capable of receiving even the sharpest bend. The sand is, of course, emptied out when this operation is terminated. The lower end of this worm is attached to a tap which passes through the vessel near the bottom. The upper end is soldered to the bottom of a small tank formed of zinc which is fixed in the upper part of the wooden vessel, yet in such a manner as not to prevent the nitrate of ammonia and water from being easily thrown or poured into the vessel. The capacity of the tank may be such as to contain any quantity of liquid required to be cooled, from a quart to a gallon or upwards.

Whatever the nature of the liquid be from which the heat is to be withdrawn it is poured into the tank, from which it immediately descends into and fills the worm. A charge of the freezing powder is now thrown in by means of a suitable scoop, after which sufficient water is added to more than cover the powdered nitrate. After being allowed to stand for a very brief period the liquid may be drawn off by the tap, when it will be found to be in a state of icy coldness. When the refrigerating solution has served its purpose it is drawn off from the vessel into a flat metallic tray by means of a second tap quite close to the bottom of the vessel, and, as we have stated, when the water has evaporated from the solution the crystals are ready for either being used again immediately or for storage in a wide-mouthed bottle for employment at some future period.

By adopting a non-conducting casing, on the principle of the Norwegian cooking-stove, any article or fluid which has been made cold in the manner described may be retained at or near the freezing-point for several days; and, if precaution be taken to have it surrounded by a non-conducting body—such as felt, cloth, lime, or a mixture composed of them all—the vessel in which the solution is made may consist advantageously of tin or thin zinc. It must, however, be encased in a wooden shell, the space between the two being packed with the non-conducting material described. A cover, rendered non-conductive by similar means, should also be procured; and to render the apparatus quite perfect the taps must be formed, not of metal, but of ebonite.

The logical reader will at once say—"If this apparatus prove such a perfect means for conserving cold or acting as a refrigerator, would it not answer equally well for a purpose directly the opposite, namely, for retaining heat in its interior?" Certainly it will; and by way of experiment we have warmed an emulsion to nearly the boiling-point and locked the vessel containing it in the refrigerator. At the end of twenty-four hours it was found to be still hot.

We are aware of several additions that may be made to the ammonium nitrate by which its efficacy may be promoted; but as with such additions its power for being used "over and over again" becomes impaired, we recommend its employment pure and simple. If a greater degree of cold be desired than that we mentioned as the result of the first experiment, it is easily secured by employing, as the solvent of the salt, water much colder than the temperature of which we have already spoken as having tried.

PHOTOGRAPHY AND PHYSIOLOGICAL OPTICS.

In the keen discussion—which, happily, has escaped mere disputation—that has been carried on for a considerable period by various writers, and a smaller number of experimenters, very little attention has been drawn to the individual peculiarities of the eye itself. That such peculiarities do exist is well understood by those who have made a study of such matters; but the extent to which variations from what might be termed the "normal eye" do occur is popularly less known than almost any important fact connected with the vital economy. These particular characteristics have an important bearing upon photography, and we now purpose to treat of them as briefly as is necessary in the limits of a short article.

Let us turn first to the important operation of focussing, which, it is a matter of common experience, some persons never do perform correctly. This, be it observed, is not necessarily through any want of skill, though many photographers are provokingly careless over it, as it may arise from a want of power in the eyes not thoroughly appreciated. Few persons will acknowledge the necessity for the use of spectacles when they really have long been in need of them, and they may be seen "tromboning" their newspapers in a painful manner all the while they are declaring their eyes are as good as ever. But it is difficult to "trombone" the focussing-glass, and, as they will not adopt any optical assistance, their focussing is, as a matter of course, imperfect. If it were more generally understood that very soon after adult years are reached almost all eyes gradually become less near-sighted—or, in other words, lose their power of accommodation for near objects, until the average closest distance at which objects can be seen clearly defined is increased by degrees from five inches to two feet or more—there would be less false shame on this point.

It is commonly observed how large a number of Americans wear glasses, and must, therefore, have inferior sight to that enjoyed by Englishmen; but such a conclusion is by no means necessarily correct. The chances are all the other way—that the Americans wear glasses when they can be benefited by them, while English people wait till their eyes are injured before adopting spectacles. With the head under the focussing-cloth the ground glass can rarely be seen comfortably beyond six or eight inches away: and we are bold enough to say that clear vision is by no means common at that distance. The photographer, in many cases, should either wear spectacles—eye-glasses if he like—or make use of a focussing-glass: there would be better focussing and greater comfort.

We may here note that it is by no means uncommon for the eyes in one individual to be of different foci. A well-known contributor to these pages can see objects quite clearly when brought within six inches of one eye, while with the other he cannot see clearly at a nearer point than eighteen inches: hence, when he desires to examine a negative, he only makes use of one eye—that with the shorter focus. Others, again, suffer from astigmatism—an exceedingly common peculiarity; in fact, few persons are entirely free from it. This is another fault which, when existing in a pronounced form, would interfere with the power of discriminating the good qualities of a lens rather than with that of correctly focussing. All of these defects, however, may be turned or counteracted by the use of suitable optical aids; and if our remarks should only cause one single photographer to cease straining his eyes and use glasses to help him we shall be well repaid.

In no case are they more needed than with the retoucher. Many are the instances where the eyes have prematurely broken down, and the cause attributed to the strain of retouching, when all such strain could have been removed by the use of spectacles. A strain is put upon the internal muscles of the eye when they are continuously employed in looking at near objects; and where, for the sake of obtaining a larger image, the face is brought near to the negative the strain is so great that the muscles relax and gradually lose their power of accommodating the eye for near objects. We assume our readers to be aware of the fact that the eye has to be focussed for near or distant objects just as has the landscape or portrait lens; but, unlike the latter, the ocular focussing is self-acting within its own limits. This focussing, as a valued contributor once suggested, would be awkward if it had to be performed by a rack-and-pinion placed across the nose, and it is done in a far more wonderful manner.

The lens itself, which lies within the eye, just at the back of the iris which forms the stop or diaphragm, the small black circle or centre termed the pupil being the aperture of this diaphragm, is self-acting, elastic, and, according to the requirements of the case, capable of becoming more or less convex, automatically. This is done by certain muscles which are only at rest during sleep or when distant objects are being viewed, and the nearer the object the greater the extent to which these muscles are brought into play. There is a point beyond which they cannot work, just as by the muscles of the limbs a certain weight can be lifted; though no strain whatever can enable them to lift any heavier weight. If a persistent attempt is made to push their action beyond that point they suffer, though when it is not too frequently or continuously approached, and the eye used for distances where it is not greatly exerted, no evil can result unless there are hidden defects calling for the physician's services.

We feel very strongly on this point, for we have seen so many cases where the eyes have been injured in an utterly needless manner. Some may object to our advice and say that the way to strengthen muscles is to exercise them; to which we reply that it is only true up to a certain point. Many young would-be athletes attempt to strengthen their muscles by wielding immense dumb bells or Indian clubs; but any professor of athletics can tell such experimenters that they would obtain greater power by practising for a longer time with lighter instruments, while many a physician can show the actual bodily injury done by such practising. So it is with the eye. Let it be used much and often, as indeed it is intended evidently to be, but let it not be strained. At retouching, and all other work requiring the eye to be brought near to the object, let spectacles be used, the gain will be as great in comfort of working as in avoiding an injurious strain.

We have dwelt so long upon this phase of the subject that we have not left ourselves space to treat of the interesting topic of colour-blindness, so closely connected with dark-room illumination. This we propose dealing with in our next issue.

The pass list and examiners' reports of the recent City and Guilds of London Technical Examinations have just been issued. Photography again plays a prominent part, and it is satisfactory to learn from Captain Abney's report that systematic teaching has brought about a great improvement in the standard of knowledge. In 1884 there were altogether sixty-one candidates as against fifty-four in 1883. Of these twenty-two passed for the first time, while a large number improved the positions gained in previous examinations. The great majority of the candidates in photography belong to London, where the special facilities offered by the Technical Institute and the Polytechnic form an encouragement to enter on the study of photography.

The presence of a plumber in the photographer's dark room or in his studio is always attended with a considerable amount of inconvenience, not to speak of the inevitable bill for workman and apprentice—charged at least half-a-day each for work which to the uninitiated would seem not more than could be comfortably accomplished by one man in a few minutes. Mr. Fletcher's laboratory taps, which one can apply himself by means of a short length of india-rubber, without calling in the aid of a workman, are most useful and should be more widely known. Still another convenience appears to be now in course of manufacture in America in the shape of paper tubes, which are made by passing bands of paper through melted asphalte, winding them on a roller, submitting them to pressure, cooling in water, and, finally, removing them from the roller and coating the interior with an impermeable substance. These tubes are absolutely watertight, very resisting, and much less costly than metal.

We hear, too, of another American invention which, if it approach in usefulness the promises made for it, ought to find a place in every photographer's studio. It is a "hand grenade fire extinguisher." Every photographer knows the risks supposed to underlie the use of photographic chemicals, as witness the heavy charges of the insurances companies; hence a portable and always available fire extinguisher would, if effectual, be of incalculable value. The "hand grenade" consists of a glass flask of somewhat ornamental appearance which contains a pint of the extinguishing fluid. This fluid (a chemical mixture) is of such a nature, it is stated, that on being distributed over a fire carbonic acid is generated, whereby the fire is rapidly extinguished. The contents are explained to be entirely harmless to flesh and fabric. A trial was lately made on a vacant piece of ground near Farringdon-road, and the results were highly successful. We shall, no doubt, hear more of this invention ere long.

We have often referred to the solubility of glass in water, and we may here give the results of some experiments of Herren U. Kreusler and O. Henzold on the subject. Finding the results of some experiments they were carrying on vitiated by some unknown error, they found the cause to be the solubility of the glass, and in investigating the matter thoroughly they found much variation in the solubility of different kinds of glass. It is easy to see how the results of a photographic experiment might be similarly affected, a solution supposed to be neutral giving decidedly alkaline reactions owing to the dissolved glass. They tried (1) readily-fusible Thuringian glass; (2) less fusible Thuringian glass; (3) combustion tubing of very refractory Bohemian glass; and (4) more readily-fusible Bohemian glass. Of these the first was far the most readily attacked by water, the third being the least attacked. The fourth was nearly as good as the third, while the second was much more readily acted upon. The alkaline reaction of glass, they state, may be readily seen by boiling red litmus solution in a test-tube, and by other such simple experiments.

"An ounce of chrome alum, quarter of an ounce of citric acid, half-a-gallon of water, according to the suggestions of a leading article in your Journal, form an invaluable bath after developing. Give the merest rinse under the tap, drop the negatives in this solution, leave them there for a few minutes or an hour, and I am confident that they will not frill. They will not, either, if left unfixed, go on developing till they become too dense; and, further, they will not have a trace of yellowness, and will possess all the wet-plate character you may think necessary." So writes a correspondent, and a continued series of trials of the bath in question enables us to endorse all he says. We may give one caution, and that is to give a full washing after the dip or the sulphur may be precipitated in the film when the negative is placed in the hypo. Most photographers are aware of the continued action of the developer which takes place if a negative is left long unfixed, even if water be left running upon it for the whole time. Those, therefore, who try this plan—and may have been in the habit of leaving their negatives for some time after developing before placing them in the hypo.—must make due allowance for the fact that this bath arrests development at once. We point this out lest we may be told that the solution reduces the strength of the negative. It does not touch the image in the slightest.

Melted snow is supposed to be one of the purest forms of water when collected under suitable conditions; but the following particulars of the analysis of snow collected with every precaution will show that snow water is not necessarily an article of complete purity, The sample was collected in the yard at Columbia College after it had been snowing for three or four hours and snow was still falling. It was taken up without being touched with the hands, and was placed in a large stoppered bottle, which was then closed and placed on a laboratory shelf till the snow was melted. The water was slightly turbid, and, after being allowed to settle, was examined, every precaution being thus taken to ensure the absence of contamination of any kind. The results (in parts per 100,000) were—

Chlorine	Trace.
Phosphates	None.
Nitrates	„
Nitrogen in nitrates	·0494
Free ammonia	·0396
Albumenoid ammonia	·0318
Hardness	·91
Total solids	6·3

It will thus be seen that this would be by no means suitable for experiments where pure water formed a basis of working.

GALLIC ACID IN THE DEVELOPER.—A NEW RESTRAINER.

The intimate connection between pyrogallic, gallic, and tannic acids, from a chemical point of view, would suggest that their behaviour as developers should be in some manner similar. But surely this latter is not the case. True, both gallic and pyrogallic acids have found their use in the old form of silver development ("physical" development is it not called?), and tannin has been put forward as a "sensitiser" of previously insensitive iodide of silver. Yet, on the other hand, when we turn to chemical development, tannin is not only useless but has years ago been shown to be a restrainer, and gallic acid has not apparently proved much more effective, if we may judge from its pretty general disappearance from the photographic laboratory, while pyrogallic reigns supreme.

In the course of some experiments with tannin and gallic acid as additions to the ordinary pyro. and ammonia developer, for the purpose of altering the colour of the image, I found certain peculiarities belonging to each. I commenced these experiments remembering the variety of beautiful colours occasionally obtained under certain conditions of exposure and development with plates prepared by Major Russell's rapid dry process. These colours varied from all and every shade of brown, through different grades of red and purple, to the purest crimson or magenta ever produced by the dyer. Major Russell himself, in his *Tannin Process*, published, I think, in 1863 or 1864, called attention to the colour effects produced by the admixture of the three substances I have named—gallic, pyrogallic, and tannic acids—when present together during development (whether originally employed in the preservative or in the developer matters not) the coalition of the three—or two of them—sufficed to give effects that could not be obtained with any one singly.

But I may at once say that with gelatine plates I have had no success whatever in my attempt to secure tones not obtainable with pyro. alone. Why this should be in the case of gelatine plates I cannot pretend to say, especially when I know from actual practice that with dry collodion plates and the same, or very similar, development particular tones could be got with almost certainty when tannin and pyro. were present during development. The result depended chiefly upon the exposure, as seems to be the case with the modern gelatino-chloride plates and ferrous citro-oxalate development. At anyrate, the fact to me is pretty plain that gelatine and collodion plates are quite different in their behaviour under similar treatment.

While engaged on these experiments I happened to come across, in a back volume of the Journal, some editorial remarks on the use of gallic acid and ammonia as a developer for collodion dry plates. Seeing the relative prices of pyro. and gallic acid are very different, and with the prospect that the vagaries of gelatino-bromide might possibly result in my discovering that gallic acid was a more powerful and valuable developing agent than pyro., I "prospected the ground." With what result? Well, astonishment at least. I may as well detail my experiments.

A plate of known value as to sensitiveness was exposed for the normal time, and a developer of the ordinary character, only substituting gallic for pyrogallic acid, applied. Saturated solution of gallic acid was used instead of pyro., and ammonia and bromide added in usual quantities. The result as regards image was absolutely *nil*, though the ammonia was "piled on" until it would have fogged any decently-ordered plate if pyro. had been used instead of gallic acid. I thought I must have made some simple omission in the process of exposure—probably had not drawn the shutter; so I repeated the experiment, exposing a plate, cutting it in halves and developing one with pyro., and *failing* to develope the other with gallic acid. The latter half of the plate was washed and treated with the ordinary pyro. developer, when a clean, under-exposed negative resulted, though the other portion of the plate had been fully if not overdone.

This result set me thinking as to the possibility of gallic acid proving a practical restrainer for over-exposed plates; and in the end, to cut a rather long description short, I found it to be not only that but more. It is a restrainer of a very powerful character, and it may be used *in conjunction with pyro.* to give vigour and density with a very small proportion of pyro., if time be no object. Thus, half-a-grain to the ounce of pyro., supplemented by gallic acid, will give a negative of far greater vigour than a three-grain pyro. solution if a little time be allowed for its action. This, however, is not an important application.

In cases of known over-exposure the addition of a certain quantity of gallic acid to the ordinary developer will prove as effectual as citric acid; or the plate may be soaked first in gallic acid and then developed in the ordinary manner. As an instance: I today exposed a plate very fully, cut it into three portions, developing one in the ordinary manner, treating it as a case of *known* over-exposure; the second with half the quantity of pyro. with the addition of gallic acid; the third was soaked in gallic acid first, washed, and developed in the ordinary manner. The first is thin and feeble from over-exposure; the second and third, though five or six times the quantity of ammonia had to be used, are strong, vigorous negatives, without a trace or symptom of over-exposure.

H. Y. E. Cotesworth.

SOME MYSTERIES IN CONNECTION WITH GELATINE EMULSION.

I have been engaged for some time past in trying to find explanations for several uncertainties and difficulties I have met with when making and using gelatine emulsion. I thought if I could find out the causes of the difficulties it would be the greatest step towards finding out a way of removing them, and I could then have some hopes of knowing what points to be particular about to obtain an emulsion of a good quality with some degree of certainty.

The first point I took up was one raised by the chairman of the Leeds Photographic Society some time since, asking how it was that a plate exposed in the camera, and then put by in the dark for a time, if again exposed would on development show no trace of the first exposure.

We know that if we wash the plate in a solution of bichromate of potassium it will eliminate the effect of light, and the question at once arises—if, as many suppose, the action of light converts the silver bromide into a sub-bromide—What action can the bichromate have on this sub-bromide to reconvert it either into pure bromide of silver or an equivalent, as far as photography is concerned?

From the first it has appeared to me that the action of the bichromate must be only to act on the gelatine; and, if by putting the plate away in the dark for a time it had the same effect, I argued it must be through an atmospheric action on the gelatine. If it were so, I thought I ought to get the same result by scraping an emulsion which had been acted upon by light from the plate, and by simply remelting it and recoating the plates. It would go far to prove that the bichromate and atmospheric action must be only on the gelatine, and would cause grave doubts as to whether the action of light on a plate by exposure in the camera is really to reduce the bromide of silver to a sub-bromide when the invisible action takes place requiring development.

Perhaps I had better explain at once that I believe the chemical action or reduction to a sub-bromide probably commences in what we know as the "reversed action of light," and is the same as the action which takes place on a daguerrotype plate; but that light acting on the salts of silver, when held in suspension in collodion or gelatine, has a previous mechanical action—namely, the rapid vibration or expansion of the particles which strain or burst the protecting cells of the collodion or gelatine—and that the action of the bichromate of potassium or the atmospheric action, if plates are left in the dark for a length of time, repair, so to speak, the cells of the gelatine which protect the particles of silver bromide from the action of the developer the same as before they had been acted upon by light. I will not take up space by stating all the experiments I have made to test these questions, but will only give some that have an important bearing on practical work.

I made up an emulsion, and to make the experiments as effective as possible the gelatine used in emulsifying was first boiled in ammonia and water to decompose the gelatine, so as to obtain a rapid (or blue) emulsion. The potassium bromide was now added to the gelatine, then the silver nitrate in crystals, and the bottle well shaken up. The bulk of the gelatine was then added, the whole of the operations, so far, being conducted in the bright white light of a paraffine lamp (this I believe, however, has been done before). The emulsion was now put aside to set in the dark. I decided not to wash it in bichromate of potassium solution, because I wanted to clearly test the part the gelatine acts in an emulsion. I washed it, therefore, in plain water, and then remelted it. I coated some plates in the dark room in the usual way. I then coated some others close to the white light of a paraffine lamp, but put them to set in the dark room. When they were set I exposed one of them behind a negative for eleven seconds. On development I got a very dense transparency showing through to the back, so I knew that the whole of the particles of silver bromide would be acted upon by the light in eleven seconds. To be quite sure, however, I exposed three of the plates, which had been coated in white light, eighteen inches from a powerful gas flame for two minutes. I then scraped the emulsion from the plates and warmed it up again for two or three minutes, recoated the plates, and put all away in the drying-box. When they were dry I exposed the plates coated in the dark room, those coated in white light, and the remelted ones for the same length of time behind the same negatives.

On development the plates which had been exposed for two minutes to the gaslight were as perfect as those coated in the dark room; so we see that by simply remelting an emulsion which had previously been exposed to white light, and thereby repairing the gelatine surrounding the particles of the silver salts, we can eliminate the effect of light, the same as is done by bichromate of potassium or by leaving the exposed plates for a length of time and then re-exposing.

There was a slight fog on all the plates, but no more on the remelted ones than on those coated in the dark room. This shows that the emulsion was in fault; but as it was prepared in bright white light, and not washed in bichromate of potassium, there was much less fog than I expected, because, probably through boiling the gelatine in ammonia and water too long, it was so decomposed as to almost reach the grey stage.

As far as my experiments extend, it seems that all the time an emulsion is kept above 90° or 100° white light acts on it only very slightly, if at all; but directly it commences to set even the chill caused by the cold glass (if the plates be coated in white light) is sufficient to cause a slight fog, because the action of light on the particles at once causes them to strain the gelatine.

The same action seems to take place in the case of collodion emulsion. One of our editors told me some time since that he accidentally left a bottle of collodion emulsion in bright sunlight for several hours, and on coating plates with it they only showed a very slight fog. Of course if he had coated some plates, and after they had set exposed them to daylight for a second or two, they would have been hopelessly spoiled, although the same emulsion, when kept in a fluid state, can be exposed for hours without injury. So it will be seen that at least in the preparation of both gelatine and collodion emulsions we shall be able to save our eyes from some of the injury caused by the prolonged work in the dull light of the dark room, and we have here a useful field for further experiment.

I ask how does the theory of a reduction to a sub-bromide explain these facts? or how does it explain the result of friction on a plate? As these questions have been raised lately in connection with the packing of dry plates I will state several points that I have noticed on the subject:—1. It seems to act more on rapid than on slow plates; indeed, with the latter I have never noticed it. 2. Large plates are worse than small ones. 3. The bottom plates in a box show this slight fog often when those taken from the top are all right. I have noticed this several times, and possibly we have been blaming plate-makers for inferior plates when the fog has been due to friction. 4. A batch of plates with streaks of emulsion on the back are worse than those without. So I have come to the conclusion that if the packing-paper between the plates do not entirely cover them, or if the substance of the paper be at all lumpy, or if there are streaks of emulsion at the back of the plates, slight friction is produced by them moving slightly in the boxes, especially in the case of large, heavy plates. In transit this slight movement would produce a continued grinding of the fibre of the paper (and the emulsion on the back of the plate) against the film, fracturing the thin gelatine cells covering the particles of silver bromide, and the developer would act upon those particles the same as if they had been acted upon by light, fog being thus produced. If strips of thick cartridge-paper are put at the edges of the plates fog will often be found where the paper touched, and sometimes a little beyond it, which shows that there was a slight movement of the plates.

Possibly, in some cases, a chemical action may take place between something in the packing-paper and the film which will produce fog; but I have not been able to discover any with any packing-papers I have met with. If there be a chemical action, by laying a piece of the paper on the plate and leaving it for a time fog ought to be produced; if it be not, the fog must be produced by friction when that sample of paper is used.

I have tried several sorts of paper to put between the plates, but I now simply put a piece of velvet or other soft substance at the bottom of the box, clean the emulsion from the back of the plates, lay them one on the other, face downwards, and then wedge them carefully in the box, so that they cannot slip about. The smooth surface of the glass certainly appears to be better than paper to be in contact with the film; besides, they are less likely to suffer from the effects of damp than when a soft, porous paper is between the glass and the film.

DARK-ROOM ILLUMINATION.

I did not intend to again take part in the discussion on this subject; but I would like to take this opportunity of correcting a mistake in your report of a meeting of the London and Provincial Photographic Society a few weeks ago.

It will be remembered that, in April last, I called attention to the fact that if we threw the blue and yellow rays of the spectrum *on one spot* we obtained a pure white light. I also mentioned other combinations of colours which have the same effect, and of these various combinations I stated that if we could get pure colours the white produced by red and yellowish-green (of course when thrown on one spot as with the rays of the spectrum) would be the safest for photographic purposes. In May Mr. W. E. Debenham showed a lamp with two lights—one passing through red glass, the other through yellowish-green, thrown on to one spot as I proposed—and demonstrated that the nearly white light produced by the impure colours of the coloured glasses was safe for practical development.

In the report of the meeting I was made to say that both Mr. Lewis Wright and the Editors objected to my statement. This was wrong as regards the former gentleman, because he kindly showed in his article how my suggestion could be made thoroughly practical. It never struck me how strange the proposal must seem to a photographer used to the Egyptian darkness of his dark room, because for months I had been using a very light yellow reflected light with safety.

As to my suggestion that the reason of Mr. Debenham's combination of yellow and green being whiter (or of a lighter tint) than either colour when used alone is due to the same law (though of course under different conditions) is another matter which I will not go into. I never meant for one moment that if any coloured mediums were put one in front of the other they would produce white light. What I said was that, in the case of the yellow and green, they produce a whiter—that is, a lighter—tint than either colour alone.

I think the use of reflected light is much overlooked in connection with dark-room illumination. By using transmitted light, when the plate is placed within two or three feet of the source of light, we have to put screens to make the *direct light* safe which passes from the source to the plate and the room is in darkness; but by using reflected light in daylight we can have a flood of light first dispersed throughout the room, and have only to be careful that the weak light reflected from any small surface of the room on to the plate is sufficiently non-actinic for ordinary development. HERBERT S. STARNES.

ON PHOTOGRAPHING THE OUTLINES OF COASTS AND HEADLANDS FROM THE SEA, AS CARRIED OUT BY THE GERMAN IMPERIAL NAVY.

THE outlines (profiles) of coasts and headlands are of as much importance to mariners as sea charts. Frequently these outlines are drawn upon the charts, and the necessary views have been generally obtained from sketches the accuracy of which has depended upon the skill of the sketcher and upon the more or less favourable circumstances under which the drawing was made—circumstances which generally left a good deal to be desired. The greatest drawback to these sketches was that they had to be done from the deck of a ship in motion.

The idea then occurred that instead of sketches the more rapidly-made photograph might be used, especially as the modern dry plate, with its instantaneous exposure, might admit of a view secured from a sailing vessel being considered as taken under favourable circumstances. As a matter of fact, in the spring certain attempts in this direction were made by the imperial marine, but no satisfactory results were obtained. An ordinary landscape camera and camera-stand had been furnished for this purpose, along with a lens of relatively short focus (about eight inches), which, though suitable enough for working with on land, was not so for working on shipboard, where the motion of the ship offered the greatest difficulties to the setting up of the apparatus, and still more so to the sharp focussing, especially when the whole business was to be done, not by experienced professional photographers, but by seamen. The pictures obtained were too small for the purpose for which they were intended; they were not sharp, they were often over-exposed, and, in short, they were unsatisfactory.

The task set was evidently that of taking a long horizontal stretch of coast line, the height of which is insignificant compared to its breadth, and which must be at least a sea mile distant from the operator. The ordinary size of landscape plates, which are about as high as they are wide, are not at all suitable for this purpose, as they give much useless sky and foreground. It was further evident that, as it was a case of taking the views from a considerable distance, it would be possible to focus the objective for the far distance while on land, and to fix it at that focus once for all, thus rendering focussing on shipboard unnecessary. Also, the wish to obtain as large pictures as possible of the different features of the coast justified the choice of a lens with a long focus.

These were the considerations which weighed with me when I was asked to recommend an apparatus that should be especially suited to taking views of the outline of the coast from a ship in motion. Accordingly I designed a keel-shaped, flat camera, without extension, for plates ten c.m. high by forty c.m. wide. From amongst the lenses at my disposal I selected that which had the longest focus, viz., an ordinary Steinheil aplanatic of fifty-four c.m. focus. In order that the camera should not follow the motions of the ship it was borne upon a rod four feet long, which terminated above in a spherical projection. This rested upon a perforated, hollow, spherical socket. To the rod that passed through the hole was attached below a hook, to which half-a-hundredweight was suspended. The socket rested upon a broad stand screwed firmly to the deck. By means of the heavy weight, in spite of the rolling of the vessel, the rod was kept in a perpendicular position, and consequently the camera screwed to it was kept level.

The fine focussing was unnecessary; all that was required was to focus the field of vision. A binocular upon the camera served to get the rough focus with, an unfilled-in frame having a couple of threads crossed in the middle of it being placed opposite. On looking through the binocular one could see almost exactly the same piece of the landscape that was delineated by the objective upon the plate. The instantaneous shutter selected was Guerry's. It, however, did not do so well as was expected, as the shutter was often blown close by a strong wind at the wrong time.

By some experiments made on land it was proved that with Sach's plates, even when the next to the smallest stop was used, an instantaneous picture could be obtained in good weather (at the beginning of April). The apparatus had no changing-box, but had six double dark slides, and the whole thing was made by Herr Stegemann, whose old reputation was well sustained by the work turned out on this occasion. Herr Schmid, an engineer of the imperial navy, had some practice on land, in the laboratory of the Technical High School, in using dry plates with this apparatus, which has been found to answer the purpose excellently, the outlines of 150 coastlines having been taken with it by him. In dull weather, or at late hours, a larger stop than the next to the smallest was used. Of course then one part of the plate would be sharp; but that did not matter when the object to be photographed was not very extensive.

Of course many of the plates were over-exposed and many under-exposed, when the state of the light was wrongly estimated, and when, consequently, either too large or two small a stop was used. Still the great majority of the plates were to be considered undoubtedly successful, especially if the difficulties of exposing were taken into account.

It was seen that good instantaneous views of small vessels, such as our gun-boats, which lie very unsteadily in the water, could only be taken when the machinery was stopped for the instant in which the exposure was made. Some of the plates were developed on board, a small dark room having been fitted up there. The washing took place in a closed grooved tin box through which a continuous stream of water was pumped by machinery. This contrivance also answered well.

Thus a new and interesting field of work has been opened up for photography, and it is to be hoped that the examples given will soon have imitators. H. W. VOGEL, *Professor.*

—*Mittheilungen.*

TOURISTS' CAMERAS.

ONE of the last strong expressions of opinion published by the late H. Baden Pritchard was that the tourist's camera of the future has yet to be constructed. There can be no doubt of it, unless some meritorious camera is somewhere lost to sight and to public view. It is one thing to find fault without being able to point out a remedy, and another thing to find fault justly, with a full knowledge of what is wanted and the certainty that manufacturers can meet the want if they have the will. Some two years or more ago I called attention to this subject in these pages, and, having since then had much experience at tourists' work in photography, return once more to the attack.

The glaring, the vital, fault of the present tourists' cameras is that they waste so much of the time of the user in the adjustment of various parts over each view, also in unpacking and repacking. Ten minutes' waste of time over all this may, perhaps, be taken as the minimum; the maximum may be twenty or more. This waste of time, amounting to an hour or more over the exposure of the usual six plates in the three double dark slides, is a permanent grievance in itself, with several minor disadvantages. One is that the time occupied in fixing the apparatus in or near villages and populous places gives more time for a crowd of spectators to assemble, when the operator would prefer their absence. When the Rigi railways were under snow I ascended to Rigi Klösterli with photographic apparatus, and in one place where the path passed through a wood came across a beautiful scene. The delicate twigs of the underwood bending under a weight of snow in the foreground, the white Alps near the entrance of the St. Gothard district in the distance, with the lake in the valley below, and precipices covered with snow-white trees in the middle distance—all was white; everywhere white predominated, with the close foreground of fairy beauty. Yet I knew that taking the view meant standing still for at least fifteen minutes in the bitter cold, with feet in the snow as far as they could sink; and, as it was difficult to keep warm even with incessant walking, the scene was unwillingly left unphotographed—all in consequence of want of intelligence on the part of the maker of the apparatus. Every man who buys tourists' apparatus should try on the premises how long it takes to remove it from its case, to adjust it on the top of the stand, to take it to pieces, and to pack it away again. This should be done in the shop before the would-be vendor, the time taken by a watch, and a calculation made as to how much time would be thus occupied over six views.

Parenthetically, it may be of interest if I quit the subject here for a moment to place on record two phenomena witnessed on that long walk. I had forgotten to bring any snow spectacles with me, to protect the eyes from the glare of white by the neutral tint of the flat glasses; consequently, after one or two hours' climbing, the glare became blinding, the eyes had to be closed altogether for a time, and afterwards slightly opened, just enough to see the way. On finally reaching the inn at Rigi Klösterli and standing in its dark passage, with a door and window at the other end, that window appeared a beautiful scarlet colour, which quickly changed to a bright green. In one sense it was a pleasing sight, but in another an uncomfortable one; because it is not pleasant to have anything the matter with the eyes, even though it be but temporarily. In a few minutes, however, the eyes were in their normal state. Some of your scientific London readers were acquainted with the late Cromwell Varley, the electrician. A few of the last days of his life were spent in this village, when we visited it together, and the object of my return to it last winter was to take a few photographs there to present to Mrs. Varley. In the winter the village contains but eight inhabitants, two of them monks at the Rigi Klösterli pilgrimage church of Our Lady in the Snow. Every morning they called the inhabitants to mass by sounding a wooden rattle.

As to the effect of the glare of fallen snow upon the eye, some habitual Swiss mountaineers admit they ought to use snow spectacles, but that they often forget them. This causes them to walk about in the hills with their eyes nearly closed, and in some instances they cannot drop the habit in the plains, so that when their countenances are also good tempered they have a persistent, waggish look, as if perpetrating a perpetual joke.

The other phenomenon *is* connected with my subject. In rain the atmosphere is clearer under trees, as a rule, than in the open country. This is not so in fine weather, when the trees are covered with dry snow in high altitudes. After missing the photographing of the scene previously mentioned I passed the borders of a pine forest—white above, with dark stems below—and it was possible to see some little distance into the forest between the slender stems. A passing breeze now and then brought down a mist of fine snow-dust from those trees it chanced to agitate most, so that at some places the interior of the forest was seen through a peculiar veil of pure white, whilst at other places its depth could be penetrated by the eye as before. Here was an effect I had never seen in any photograph. I walked on, carefully watching the local snow mists under the trees, but did not attempt to photograph the scene because the camera-maker had, as already stated, turned out apparatus admirably adapted for the freezing of the user thereof.

Perhaps the gentlemen who make cameras may look on complacently at the troubles of tourists who have to use them, until somebody listens to the wail of the distressed, and, by making the first good instrument, turns the tide of popular favour all in his own direction. This matter practically affects others than tourists, namely, the makers of dry plates. With apparatus free from the general defects I should have exposed about a gross of dry plates per month more than I actually used, and mine may not be a solitary instance. The defects preventing the use of more plates were two—firstly, the waste of time over each plate already mentioned; secondly, the absence of thin glass plates for tourists, so that two plates should weigh about the same as one of the present normal type.

Considering that the market of the whole world lies open before him, and that a good tourist's camera might also be used in studios, some intelligent man among optical instrument makers or workers in wood may arise and, after devising a camera as perfect in all its parts as scientific ability and close thought can plan, erect machinery for turning out the several parts, on the same principle that the Americans, above others, often make fortunes, as in their machine-made watches, pencil-cases, and so on. An astute Swiss doctor told me that he believed that the day of making fortunes in any way by hand labour is nearly extinct within the area of civilisation, and that henceforth it can only be done by brains, with personal or other hand labour as the servant. The sooner brains have something to do with the construction of tourists' cameras the better.

To save time in unpacking a tourist's camera from its case, and subsequently repacking it, it might all be inside the case ready for use. By simply pulling out one sliding end of the case the lens might be exposed to the view, and by pulling out the other sliding end the focussing-screen might be exposed to the eye of the operator. If the lens then in position be not the one required, one of the others mounted on the rotating disc, described recently by the Editors in these pages, might be turned into its place as rapidly as the clicking of the spring which then holds it in its proper position. Behind it should be a shutter for long or short exposures, which shutter is available for use with all the lenses, and so made as to render caps for the lenses unnecessary. The camera being ready for use inside its case, the present numerous side adjustments might be abolished.

The lenses should be mounted in something less oxidisable and much less heavy than brass. The camera should either spring into its place upon the top of the stand—say by a bayonet joint—or there should be a conical hollow to guide the ordinary screw into its place, so that the operator has not to fumble about before getting the screw into position. The head of this brass screw should have a hole in it, to run a string through, when it is desirable to suspend a bag with a stone in it to steady the camera in windy weather.

The focussing-glass should not be fixed in its frame so as to give the operator much trouble and loss of time should it get smashed. It ought to slip out easily so that another could be put in its frame at once in case of breakage. All the more necessary screws should be in duplicate, so that outdoor operations shall not be suspended by the loss of one. The focussing-glass should never be of ground glass, which is well known to be too coarse for accurate work; it may be glass coated with a thin film of pure gutta-percha, from a solution of that substance in chloroform, or some other film of equally good character for the purpose. The focussing eyepiece should have an eyecup to it, so that it may not be necessary to put the head under the focussing-cloth when using it.

The dry plates, as already stated, should be of half their present average weight, and there ought to be no springs in the slides near the centres of the thin plates likely to bend them with pressure. The plates should not rattle in the slides, since that is a proof that they are not accurately kept to focus. They might, however variable in thickness, perhaps be always brought to gently press against the front of the frame by placing a sheet—or two, if need be—of corrugated black india-rubber between the backs of the two plates.

The slides should not be of nearly their present size and weight. Paper, aluminium, or something else ought to be substituted for wood in the construction. The shutter should pull right out, with a cut-off, as in American outdoor cameras; then it would not flap about in the wind, and would not let light through in time at a worn pliable hinge. The slide should not be a slide at all, but press into its place after the fashion in American cameras. The latter arrangement is more light-tight, and there is less danger of pushing or pulling the camera out of position on its vertical axis after focussing. If the camera require turning on its side, that being discovered to be the best position after seeing the view on the focussing-glass, there should be nothing to do but to turn it on its side, as in an arrangement devised—or, at any-rate, recommended—by Mr. J. Traill Taylor. Under the circumstances, the apparatus should be such that not an instant is wasted in screwing or unscrewing anything.

The camera should screw out far enough to permit the use of a lens having a focus thrice the length of the longest plate the instrument will take, for wide-angle lenses are the ruin of pictorial beauty and of apparently true perspective. They dwarf mountains to insignificant molehills, and make short streets appear to be a mile long.

A circular spirit level should be let into the top of the camera and fixed there, otherwise it is liable to be lost, not being often required. In hilly districts, with the camera-stand on a sloping bank and no horizontal line in view anywhere, optical illusions sometimes come into play, and it is difficult to know when the camera is level.

The camera should have a falling as well as a rising front, otherwise it will often be useless at high elevations, or to photograph dock gates when the water is out, or anything much below the level of the observer. The up-and-down motions should have a longer range than is usually the case in the present cameras of commerce. The camera—or rather the lens—should have some arrangement for giving more exposure to the foreground than to the sky when desired.

The more essential parts of the camera—that is to say, those for keeping the lens rigidly at its proper distance from all parts of the plate—should be strong enough to bear a reasonable amount of rough usage. The filling-in may be light-tight cloth, leather, or anything lighter than wood. The exterior of the case is not supposed to be strong enough to bear knocking about by railway porters, since that would mean immense increase in weight. It can go in a portmanteau when travelling by rail, and when in use, being in the care of the possessor, is not likely to be kicked about. Still, the essential parts—the parts holding the lenses and plates in their proper relative positions—should be of strong skeleton framework, not liable to be deranged by an accidental blow.

Any reader of these lines who intends to purchase a tourist's camera is advised to cut out the preceding nine paragraphs, and to say to the dealer—"I want a camera like that." I wish he may make the acquisition. Failing to do so, he may go through the paragraphs sentence by sentence, asking, *seriatim*, whether the camera offered for sale has each convenience mentioned, and, if not, why not. These paragraphs will serve as an aid to memory over various little points which otherwise might be forgotten at the moment, and a good camera-maker will be delighted to show that none of these points for the benefit of the purchaser have been overlooked in his instruments. I have not that camera-maker's address.

If special machinery were made to turn out the parts for the model cameras intended to be sold at moderate prices, on the same principle that the Americans have brought so much influence to bear on the Geneva and Clerkenwell watch trades, separate sets of machinery might be necessary to turn out such cameras of different sizes, so one or two good sizes might be selected in the first instance. Mr. Frith, with his very great experience, prefers eight-inch by five-inch plates. A smaller useful size might be the half-plate. Carriers could take plates of various other dimensions, including some for continental plates, for use where plates of English sizes are not obtainable. In designing a model camera the experience of a good philosophical-instrument maker should be obtained. Ordinary cameras are not yet instruments of scientific precision; they have not such accuracy, for instance, as displayed in the fittings of the camera made for Lord Lindsay, by Mr. Browning, for photographing one of the total eclipses of the sun. There were points in that instrument which might be introduced into ordinary cameras with advantage.

The new camera might be made on the principle of the Deacon's "One Hoss Shay," namely, that the reason a thing wears out and breaks down is that one part goes first; consequently the right plan is

> "Jest,
> To make that part as strong as the rest."

Anything of leather in the camera should be made of

> "Tough old hide,
> Found in the pit when the tanner died."

Anything in the camera made of timber should be constructed of

> "Lancewood, which cuts like cheese,
> But lasts like iron for things like these."

Anything in the camera requiring great strength might, perhaps, be of

> "Steel of the finest, bright and blue,
> That was the way he put her through;
> 'Neeow' says the Deacon, 'neeow she'll dew.'
> Do! She would, I rather guess,
> She was a wonder, and nothing less.
> The men who made it all turned to clay,
> Deacon and Deaconess passed away,
> Children and grandchildren—where were they?
> Yet there stood the wonderful One Hoss Shay,
> Fresh as on Lisbon earthquake day."

These lines have been merely quoted from memory, so I hope I have done the poet no injustice; if he did not write them as herein recorded he ought to have done so. The camera, like the One Hoss Shay, being equally strong in all parts, should last one or two centuries, and then suddenly fall to fine powder—

> "All at once, and nothing first,
> Just as bubbles do, when they burst."

W. H. Harrison.

THE CONVENTION OF THE PHOTOGRAPHER'S ASSOCIATION OF AMERICA.

It is too soon for us yet to receive news of what transpired at the Cincinnati convention, which was held last week, but we give the following from the *Eye* as an introduction to what may have taken place, or what, in the estimation of the writer, ought to transpire:—

Last year, at Milwaukee, much valuable time was taken up at the convention with most trivial subjects, such as any tyro in the profession ought to be thoroughly conversant with.

We take it that the convention is not convened as a school of instruction for teaching the rudiments of photography. There are many serious subjects concerning the future and present condition of our business that should be seriously considered in preference to such child-like topics as "How to Make Chloride of Gold," or how to make any other chemical used in photography. Everyone following the profession of photography ought to be in possession of some work that will furnish him such information, and if he is so unfortunate as not to possess such a book, why, then let him go to his nearest drug store and ask permission to look over the United States Pharmacopœia, and he can find out how to mix *aqua regia* to dissolve his gold if he is desirous of making his own chloride. We must confess we do not think that any man has the right to take up the time of such a large body of men on subjects that ought to be known by everyone. The most important subject to bring up is, to first put the Photographers' Association of America on a most thorough and permanent business-like basis. In the first place let us have an initiation fee; do not let it be optional about payment of dues. Let us have a society that every one will be anxious to join, and proud to hang in his rooms his certificate of membership.

We hope that some one will have something new to tell us about blisters on albumen paper; we want the conversation on this hackneyed subject changed. The subject of "How to Conduct the Printing Room" is a good one, and a most important one; we should like to see a good paper read on it. The printer is quite as important a part of a photographer's establishment as his operator, and requires just as much attention. In fact, the proper way to print is really the most important part of the work of a photographic establishment, and any one who can furnish any new and useful information to the fraternity on this most of all important parts of the make-up of your *ateliers* will be conferring a boon that would deserve a medal.

What we want is new information. We do not want subjects discussed that it only wants turning to some everyday book, which is to be found in almost any dry store, to enable one to find out the desired information.

Life is short; our time can be taken up more valuably than with trivial matters such as a good deal of the time generally is.

We do not want any one to take offence at our remarks, as nothing personal is intended for anyone. Our desire is that everyone going to the convention with the intention of getting up to make his little (or big) speech will take care to give us something new.

CARBONATE OF SODA? SAL SODA? WHAT? HOW MUCH?

Some European photographers have complained that photographic formulæ (especially when coming from England or America) are so *indistinctly expressed*, *confused*, and *irrational*, that it is impossible to work with them satisfactorily. (See *Times* for May, p. 244.) Waiving (for the present, at least) the question how far others—even Messrs. Scolik and Zwinkel—are open to the same or even graver criticism, it must be conceded that these complaints are just. Our formulæ do lack precision; they lack a correct use of chemical names, instead of a mixed use of chemical and commercial names, and a correct use of chemical weights and measures, instead of half apothecaries and half avoirdupois. If they confuse and perplex scientific and skilled photographers, what must they be to the less informed or to amateurs?

A *professional* photographer *may* get along with a formula like this:—To develope a 5 × 8 plate: put a teaspoonful of soda and a "mustard-spoonful" of sulphite into a tumbler, pour on water enough, add a "pinch" of pyro., and proceed. (The above quoted words are from actual formulæ.)

As the image comes out his practised eyes sees what is wanted, his trained hand stops at the right moment, and he adds more soda, or pyro., or water, as he sees to be necessary. He soon learns whether to take a one-finger, or two-finger, or three-finger "pinch," as the Sandwich Islander, when eating poi porridge or pudding out of his calabash, finds out whether it is one-finger or two-finger poi. At any-rate, he will know what to do next time; but the bewildered amateur is all in a fog, even with better formulæ. Not knowing what ought to be, he cannot see what *is*, nor can he judge how to make it right.

Let us take the case of the soda-pyro. developers. One of the first formulæ given called for twenty-five grains of carbonate of soda. Comparing this with others given about the same time calling for twenty-five grains of sal soda and twenty-five grains of washing soda, an amateur concluded that the ten hydrated crystals of carbonate of soda, $Na_2CO_3 + 10H_2O = 286$, were meant, and he used them. He afterwards learned that the carbonate of soda prescribed had been effloresced, becoming (nearly) $Na_2CO_3 + H_2O = 124$; so he had been using 162 grains of water instead of that quantity of the soda intended. Perhaps, however, this was just as well or better for him, but it was not just as well in the formula.

One of the latest formulæ given calls for eight grains of sal soda; another for twenty-five grains of sal soda; another for (?) grains of washing soda; another for granulated soda; and another for exsiccated soda.

Now what are all these sodas? *Carbonate of soda* in its strict chemical sense is the pure anhydrous salt, $Na_2CO_3 = 106$; but it is not in the market save in very small quantities for nice chemical processes, and probably never was used for developing a plate. In its general chemical sense it applies to all these sodas, and, therefore, is not precise enough for us to use. In its commercial sense it is now used to denote the *soda-ash* sold in New York by the hundreds of tons. Formerly, soda-ash was very impure, containing half its weight of other salts; now it is comparatively pure, containing only two per cent. of sulphate of soda and chloride of sodium, and no water. It is the most concentrated form of carbonate of soda available, and if the sulphate and chloride do no harm, and it be found desirable, this term "soda-ash"—with proper limitations—might be used in our formulæ. The name "carbonate of sodium," it should be added, has a *pharmaceutical* use. The "U.S. Pharmacopœia" and the "U.S. Dispensatory" denote by it the ten hydrated crystals. These are what our druggists put up in prescriptions calling for it; but in our formulæ it should not be used without proper qualification.

Soda *effloresced* by exposure to the air may be (nearly) a monohydrated carbonate; but its amount of water, and perhaps of carbonic acid, is variable according to the degree and circumstances of its efflorescence, and we should not use it where exactness is desired.

Granulated soda is a *commercial* term. It is commonly applied to the washing soda broken up in small pieces, hundreds of tons of which are sold to the small grocers who do not need to buy so much as a cask. It has also recently been applied to the little grain-like crystals sold in bottles to photographers, probably monohydrated crystals, $Na_2CO_3 + H_2O = 124$, with additional water, &c., from the adherent mother liquor and some small crystals containing more atoms of water. Perhaps it was called "granulated" because the manufacturing chemists would not give a precise chemical name to a variable chemical substance. Another commercial name for it is *crystal carbonate*, hundreds of tons of which are sold in New York. It is quite pure, but contains some three or four per cent. of surplus water. These forms of monohydrate may be convenient enough to call for their use, but they should be understood and precisely named.

Exsiccated carbonate of soda is a *pharmaceutical* preparation of the "U.S. Pharmacopœia" in which the ten hydrated crystals are deprived of half their weight of water, leaving what is about equal to a 2 hydrated carbonate. It is very convenient for medical use and prescriptions, but not suited to our formulæ.

Sal soda is an old *commercial term*, once applied to the less pure 10 hydrated carbonate formerly made from barilla and kelp. It was not even mentioned in the "U.S. Dispensatory" a few years ago, though in the last edition it is mentioned with washing soda, copperas, green vitriol, &c., among the common names. It is now used in commerce for washing-soda crystals.

Washing soda is the common commercial name for this form of soda; but it is applied to it in all its degrees of impurity and efflorescence.

If one selects from the grocer's cask the large, regular, clear crystals of washing soda or sal soda, or from the small grocer's box of granulated washing soda the best clear crystals, he will have a very pure and uniform 10 hydrated carbonate of soda, $Na_2CO_3 + 10\ H_2O = 286$. Will it not be best to use its chemical name?

Can we do better than to use the names, weights, and measures of the "U.S. Dispensatory," found in every drug store, and used by all physicians and druggists, and (for the subjects of which it treats) the most perfect, practical, and reliable chemical work within our reach? —*Photographic Times*. EDWIN LEIGH, M.D.

ENGINEERING PHOTOGRAPHY.*

DEVELOPMENT.

In most processes — and especially in the gelatino-bromide — the latent image is practically invisible, necessitating the use of a developer, whose use depends on the fact that after one atom of silver is precipitated it attracts other atoms as they are thrown down.

The developer first attacks the sub-bromide, shaking off one atom of silver which aids in the precipitation of others, the bromine being absorbed by the developer. The reduction of the silver bromide which has not been effected by light probably takes place according to the formula—

$$Ag + AgBr = Ag_2Br.$$

The so-called iron developer is, all things considered, undoubtedly the best for an engineer, on account of its cleanliness, convenience, and the control it gives in developing plates improperly exposed. The following is the one I use with much satisfaction:—

SOLUTION No. I.

Neutral oxalate of potash	5 ounces.
Bromide of ammonium	30 grains.
Water	20 ounces.

SOLUTION No. II.

Protosulphate of iron	5 ounces.
Tartaric acid	20 grains.
Water	20 ounces.

To four parts of No. I. add one part of No. II; place the plate in the tray and dash the developer over it, wetting the whole plate as nearly simultaneously as possible. For a 5 × 8 plate use two ounces of No. I. and four drachms of No. II. To develope an instantaneously-exposed plate increase the amount of iron to about five drachms, and add a few drops of bromide of ammonium from a solution of ten grains to the ounce; dash the developer over the plate, and as soon as it is wet pour it off. Add three drops of hyposulphite of soda, then pour it back into the tray, after which the picture will come out very rapidly.

The Cramer developer is by many photographers considered the best, and for economy and the excellence of the negatives produced by its use is certainly a very good one. It stains the fingers, and small bubbles form readily in it, like soapsuds, which are liable to stick to the plate and cause spots. It is not so good for developing instantaneous work.

* Concluded from page 491.

The following is the formula for preparing it :—

STOCK SOLUTION.

Sulphite of soda (crystals)	3 ounces troy weight.
*Bromide of ammonium	$\frac{3}{4}$ or 1 ounce ,,
Bromide of potassium	1 ,, ,,
Pyrogallic acid	2 ounces ,,
Dissolve thoroughly in pure rain, distilled, or ice water	32 fluid ounces.
Add sulphuric acid, c. p.	120 minims.
Concentrated liquid ammonia, 26° B. (sp. gr., 0·900)	3 fluid ounces.

Add water to make up bulk to 40 ounces.

Dilute sufficient for one day's use in the proportion of one part of stock solution to eleven parts of water. Use a rubber stopper for the stock solution.

FIXING.

After development the negative is washed and put into the fixing bath, which is prepared by dissolving one pound of hyposulphite of soda in half-a-gallon of water. In warm weather an addition of alum is beneficial. The hyposulphite dissolves the unaffected salts of silver. After fixing wash thoroughly.

Gelatine negatives frequently need intensifying, for which purpose I use England's mercuric intensifier :—

Mercuric chloride	1 part.
Ammonic chloride	1 ,,
Water	20 to 24 parts.

Pour the intensifier over the negative and rock the tray until the picture turns white; then wash thoroughly, after which put it in water containing a small quantity of ammonia, which turns it black.

As a rule, for engineering purposes the negatives do not need either retouching or varnishing.

APPLICATIONS.

The following are some of the uses to which the art can be put by an engineer :—

In visiting engineering works, completed or under construction, much has frequently to be learned in a short time. A few photographs of the general plan, interesting details, and machinery used in construction, showing methods of doing work, would be of incalculable value. The advantage in an engineer being able to take the views himself instead of buying them consists in his being able to get just what he wants without being bothered with that which can be of no value to him. Besides, it will frequently happen that there is no professional photographer near.

If an engineer be in charge of construction, and wishes to report progress either to a chief or board of directors, a photograph is the most accurate and trustworthy method of showing the exact condition of the work. In this case a boy could easily be taught to do the drudgery connected with developing and printing.

In case of accident to railway property, such as a washout or landslide, a wreck caused by collision, fallen bridge, tornado, earthquake, or otherwise, a photograph is the quickest way of reporting the extent of damage and condition of the wreck.

Drawings can be quickly photographed, reduced in this manner to a small scale, and made of uniform size, so that they will occupy but little room and still all the details be sufficiently well preserved to make working drawings from them if necessary. These photographs are also exceedingly convenient for an engineer who is superintending the building of machinery, saving him the bother of carrying a large drawing.

Blue prints can, of course, be made from negatives as readily as from tracings, and for many purposes are preferable to silver prints.

If a blue print be made of a machine or other object, and a pen-and-ink drawing be made on the top of it, the blue may be afterwards washed out or destroyed by immersing the picture in a saturated solution of bicarbonate of soda, which in about a minute causes the blue to disappear, leaving only the black ink lines on a white ground. Wash it carefully in water, and dry; after which it may be photo-engraved and set up with ordinary type in printing a catalogue, or elsewhere. The best ink I have ever found for the purpose is "Higgins' American Drawing Ink" ("waterproof"). The Moss Engraving Company, of New York, use silver prints and wash out with cyanide of potassium; but this is obviously inferior to the above method, which I have never seen described, and it may be new.

If autolithographic ink be used instead of Higgins', the drawing can be transferred immediately to the stone without washing out the blue. The accompanying view of my surveying camera was made in this way. For this work paper prepared for autolithography should be used.

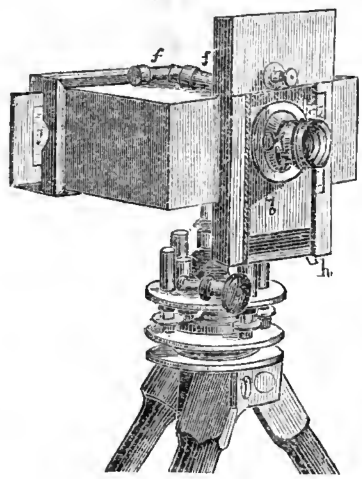
A negative can be taken from a tracing or drawing on thin paper directly by contact instead of by using the camera, prints taken from it giving black lines on a white ground in silver printing, or blue lines on a white ground in blue printing. For a large drawing the negative and chemicals for developing would be expensive.

* If you prefer intense negatives use one ounce of bromide of ammonium; but if you prefer soft negatives three-quarters of an ounce will be best, and will allow shorter exposures.

SURVEYING WITH THE CAMERA.

This being a strictly engineering use of photography, and having been but little used, if at all, in this country, and not much anywhere, is perhaps the most interesting to those present or who will read this paper. I will, therefore, now give a description of the surveying camera which I have had made for experimental work next summer, in connection with the United States' survey of the Missouri River; also the general principles and method of application, reserving the details for another paper, which, if you desire it, I will read at some future time, when I hope to know more about the subject.

In this work the dry plate must, of course, exactly take the place of the ground glass used in focussing, both of which are in the plane of the picture. It is obvious this plane must be made accurately vertical, so that all vertical lines may appear so in the photograph, and that all objects may be projected on the horizon by parallel lines. That the horizon may be accurately determined, some line, as the one through the centre of the ground glass, must be capable of being made truly horizontal. To accomplish both these ends the small levels, shown at f and f^1, are placed on the top of the camera box, the one being horizontal and parallel to the ground glass, the other perpendicular to it. The back of the box must be rigid and the focussing done by moving the lens, which is easily accomplished, since for distant objects but little change is necessary. The dry plates should, on the score of economy and convenience, be long and narrow, these I use being $2\frac{1}{2} \times 8$.



The lens should be so fixed that it can be moved up or down, for taking bluffs or mountains above the point of sight or valleys below it.

To accomplish this the lens a is attached to a slide b, moving vertically. A clamp screw is shown at c. The slide carries a vernier e which, in connection with the fixed scale d, shows how far the lens has been moved. The zero of the scale is determined by bringing the lens to the point where objects in the horizon are projected on the horizontal line through the centre of the ground glass. The slide b is held against the front of the camera box by brass springs, one of which is under the clamp c and the end of another is shown at h. The ground glass for focussing is shown at g, partly withdrawn.

The distance from the optical centre of the lens to the ground glass is accurately determined by measuring a base line in front of the camera, measuring the distance to the base line, and the length of the image or distance between the extremities as shown on the ground glass. Any change in the focal distance is measured by a scale on the side of the lens, not shown in the drawing. One of the smaller stops should be used to sharpen up the picture.

If photographs be taken with the surveying camera from two known stations, and the direction of the point of sight be measured with a transit or by means of a compass attached to the camera, the position of each object which can be seen in two pictures can be determined on the map both horizontally and vertically. The method of placing the photographs in position and locating objects is, I think, so well shown in the accompanying map that it need not be described here. [A map was here shown representing a portion of an experimental survey made at Bushberg, twenty-five miles from St. Louis.]

The draughtsman should work directly from negatives on account of the greater accuracy and distinctness of detail. The accuracy of the gelatine film on glass is so great that Dr. Eder was not able to discover any change, from developing and fixing, although by the method used he could have detected a variation of $\frac{1}{5000}$th in the distance.

By this method of surveying the plane table is virtually brought into the office, and the topographer is at both stations simultaneously, without being bothered by sun or wind.

The chief difficulty arises from aërial perspective, or the fact that distant objects appear as masses, it being hard to distinguish details. The photograph should therefore be taken when the air has little smoke or haze in it, and, if possible, when the sun shines on the back of the instrument. For nearly inaccessible mountain regions, where the air is so clear that distant objects appear very close, I think the surveying camera will be invaluable. Its peculiar adaptation to military purposes, where it is important to reduce the time of the field work, need not be pointed out.

Besides the above use of photography there are many critical moments arising in engineering practice, as where Captain Abney, R.E., tested the value of torpedoes by instantaneously photographing the column of water thrown up by the explosion.

D. C. HUMPHREYS, C.E.

FOREIGN NOTES AND NEWS.

Photography by Electricity in California.—Herr Wilde's Matt Albumenised Paper.—Herr Kindermann on Intensification with Mercury and Ammonia.—Photography at Heidelberg University.—Statistics of Photography in Switzerland.—Annual Book Fair at Leipzig.—Simple Arrangement for Packing Dry Plates.

In an amusing letter to Dr. Vogel, Herr Schoene, of San Francisco, relates how a full house was lately secured at Baldwin's theatre there. An advertisement was inserted in the morning papers to the effect that it was intended to photograph the auditorium of the theatre that evening, and every lady present would, by leaving her name and address when giving up her ticket, receive in a few days a gratis copy of the photograph taken. The thing "took," the theatre was crammed, and the photographer had a splendid puff. The operator and an amateur took their places on the stage. The electric light was turned on at three different places with such dazzling power that ladies had to spread out their fans and gentlemen had to put up their hats to save their eyes. Six plates were exposed—two in each of three cameras. Camera 1 received an exposure of fifty seconds with a portrait lens; camera 2, also with a portrait lens, an exposure of sixty seconds; and camera 3, which was handled by the amateur and was furnished with a landscape lens, gave the best result of the three with an exposure of forty seconds.

The great advantage of albumenised paper is its finely-grained surface, which brings out all the delicacy of the drawing and gradations of tone. For small work a taste for highly-glazed albumenised paper has been developed of late; but some people still consider the glossiness objectionable in large pictures. In order to retain all the advantages of fineness of surface, without the gloss objected to for large prints, Herr Wilde sensitises upon the following silver bath:—To a 1 : 8 or 1 : 10 solution of nitrate of silver add ammonia until the solution becomes almost colourless again; then add a 1 : 10 solution of citric acid in water until a slight precipitate is formed, which no longer disappears when the bath is shaken up, but leaves the latter slightly milky. To a litre of this silver solution is then added 100 c. c. of sulphuric ether. The bath is then filtered and is ready for use.

In the *Deutsche Photographer Zeitung* Herr Kindermann writes that he hears frequent complaints of plates intensified with mercury and ammonia turning brown in spite of having been *most thoroughly and carefully washed*. The cause of this he takes to be that they have not been properly fixed, and he is convinced that if the plates it is intended to intensify be left a-quarter of an hour in the soda the negatives will never turn brown, even though the subsequent washing should not be so very thorough.

Professor Eisenlohr is to give a course of lectures on photography, with practical demonstrations, as a part of the summer course at the University of Heidelberg.

Herr Boissonas reports at length in the *Correspondez* respecting the group (25) "Photography" at the National Exhibition, held last year at Zurich, and from his report the following statistics are culled:—There are now upwards of 200 photographic establishments in Switzerland employing five or six hundred men and women, and doing business to the amount of about three million francs. M. Boissonas divides these establishments into three classes, according to the turn over and the number of *employés*, thus:—1st class, twenty studios, with six to ten assistants and a turn over of 30,000 to 60,000 francs; 2nd class, fifty to sixty studios, with three to six assistants, with a turn over of 15,000 to 30,000 francs; 3rd class, 120 to 130 studios, with one to three assistants, and a turn over of 5,000 to 10,000 francs. With regard to the spread of photography during the last twenty-four years he tells us that in 1860 there were in Switzerland forty-six photographic establishments, but few or no amateurs. In 1870 the numbers had rather more than doubled, to 101 establishments, but still few or no amateurs; while in 1883 the number of professional establishments had again doubled and risen to 204, and there are now many amateurs. A natural tendency was observed for the largest establishments and best work to be found at the places most visited by the travelling public.

At the annual book fair at Leipzig an exhibition was held in which representatives of the leading firms of London, Boston, New York, Paris, Turin, Milan, the Hague, and St. Petersburg took part, and a splendid illustrated catalogue has been issued descriptive of the progress of printing and illustration, from a *facsimile* page of Guttenberg's Bible (1450—1455) to the photographic Schnell pressdruck of the present day. Amongst the lichtdrucks to which the *Mittheilungen* calls attention are some by Hoffmann, Dresden; Römler Jonas, Dresden; Rommler, Frankfort; Nauman Schroeder, Leipzig; Kochs, Pforzheim;—and autotypes of Gaillard, Berlin; Meisenbach, Munich; Angerer and Goeschl, Vienna, &c.

The accompanying illustration shows a section of a very simple arrangement for packing dry plates, as recommended to the Berlin Association for the Cultivation of Photography by Mr. Kilburn, of Littleton, New Hampshire. An ordinary box about the length and width of the plates to be packed is taken, and two long, soft, white cords laid parallel to each other across the bottom of the box, one end of each being made fast as shown by K, while the longest part of the cord hangs outside the box. The two cords are laid smooth and parallel along the bottom of the box; the first plate is then laid down upon them, and the cords are turned across over the plate, so that they hang out at the opposite side to that from which they did before. The second plate is then laid on the first one, and the cords doubled back again; another plate is put in, and so on until the box is full. To take out a plate: pull the strings, which will at once raise the uppermost plate. Mr. Kilburn says there is no fear of the string marking the plates. He has transported thousands of plates in this way, has already used about 1,800 of them in Europe, and has as yet only had one broken plate. In order to keep out light perfectly the box is placed in a second somewhat larger box, and that again in a third.

How to Foretell the Weather with the Pocket Spectroscope.
By F. W. Cory.
London: Chatto and Windus.

This little work of ninety pages will give to the reader who possesses a smattering of science a fair idea of what can be done with the spectroscope in the way of weather-forecasting. The author, after fully describing the nature of the so-called "rainband" and its position in the solar spectrum, proceeds to point out how the spectroscopic examination of the sky must not be taken by itself as a weather-guide, but that other circumstances must be noted concurrently. A considerable amount of correspondence which appeared in *The Times* in 1882 on the subject is here reprinted, and this will give to the non-technical reader a fair idea of the arguments for and against the spectroscope as a meteorological instrument. Descriptions and cuts are given of Browning's and other spectroscopes suitable for rainband observations, and the book will, no doubt, prove useful to a large section of the community who do not wish to dive too deeply into the waves of science.

Contemporary Press.

AMATEUR PHOTOGRAPHY.

[Time.]

A very fallacious notion seems to be prevalent on the part of the general public that photography is an art very nearly approaching the occult, but nothing can well be further from the real state of the case, as it is, on the contrary, a very simple and easily acquired art—I had almost said amusement—and can be learned from a handbook.

It is very fascinating, especially in the earlier days of the beginner, and the ease with which photographs can be taken by the modern dry plate process leads the tyro to roam about always on the look-out for whomsoever he may focus.

When I first took up the *rôle* of an amateur photographer I made myself a veritable terror to the neighbourhood, and those who knew of the new bent of my mind went by my domicile in fear and trembling and with an anxious aspect, just, for all the world, as if they were actually in a studio—for a portion of my paraphernalia was an instantaneous shutter, by the aid of which I was able to secure rapid views. Sunday was my great day, and just as the people began to file past on their way from church, out came my camera, and, concealed amongst the lilac bushes in my front garden, I was wont to lie in wait with a two-foot smile, like a tiger ready for its spring—and almost as much dreaded by my friends—and, so soon as a notable group came within range, click went my trigger, and lo! the picture only needed to be developed and otherwise prepared. Thus I was in the habit of producing pictures in which highly respectable and decorous old gentlemen would be shown standing on one leg, with the other lifted in the air, as if hopping; another would be pourtrayed in the form of an animated letter X, as he happened to be taken just as he was making a stride; another would be shown in the act of taking off his hat with a sweep, but appearing in the photograph as though committing a violent assault, with the said head-gear, upon the lady who was in reality being gracefully saluted; others would be blowing their noses and looking ridiculous; others, who happened to be walking past at a more brisk pace than usual, might be presented *sans* legs at all—each looking like a head and trunk with some diaphanous, cloudy-looking support that gave a very phantasmal general aspect to the object. One gentleman—who wore a white hat and who stooped in his gait—always gave the impression, in the resulting photo., that he was carrying his nose by the shortest cut to the ground; and this gentleman in particular, who was of a meek, retiring disposition, became a livid object of terrified apprehension as he neared the spot, and hastened onward in the greatest trepidation in order to avoid being, as it were, lampooned—for I took care that any striking picture was duly circulated among the group of friends.

This was of course all very wrong and unchristian, but, fortunately for my victims, many of these attempts were failures—either from one cause or another; but sufficient survived the various vicissitudes of the perfunctory treatment of the novice to "get my name up." People got at last to carefully put up their umbrellas as they passed, and all I could focus was an apprehensive nose; and those who had been in the habit for years past of grouping themselves at the corner where the cross roads divide—just opposite my house—became afraid to do so, but went a little way onward so as to be covered from the baleful glance of my searching lens—much to my chagrin.

It was curious to see those who were in the secret, and did not mind being photographed so long as they could be made to appear dignified, pass by my hiding-place. They drew themselves up to their full height, and scrupulously turned towards the possible camera their best side face, and generally placed themselves in the most romantic and interesting attitudes. But all in vain; for so fell was the spirit that then actuated the amateur photographer that, so soon as he saw them all ready, he turned the angle aside and sought for other and more noticeable subjects.

Passing traps and bicyclists were aimed at by the score, and sometimes only the hind wheel was secured on the plate; or sometimes a cart appeared to be but a square mass of fog, or the horse's legs did not show, or it had two heads, or else the plate only showed the wheels in full presence, and nothing else.

In the earlier stages of the craze, for such it was, my family fell into the groove I thus prepared for them with the greatest enthusiasm, and were ready to be photographed whenever and in whatever combination I, the *pater*, chose to fix upon; but even they—long suffering as families are to the fads of their progenitors—became at last so thoroughly sick of the constant posing and focussing, that at last it was only by dint of unlimited bribes—in the shape of sweets and toffied presents—that even the youngest of the clan could be induced to submit his rubicund countenance and podgy form to the influence of the camera. The bulldog, too, became so familiar with the whole business, that she actually sniffed when her master assumed a wheedling air, with the well-known camera and black velvet in his grasp. The times that that bulldog has been focussed would use up the computations of a multiplication table, and unhappily, as a rule, the result has been dire failure, as that very estimable quadruped generally winks, or becomes conscious of the possibility of cats and starts away, thus spoiling an otherwise unblemished photo.

As with most things that are started vehemently—and I venture to say that most beginners with the fascinating art of photography are vehement—the first hot fervour soon subsides and more moderate counsels prevails and less plates are wasted. In many cases, however, after a close perusal of the accounts of the various exhibitions—detailed at length in the photographic press—the tyro begins to be ambitious to excel, and to become an exhibitor; and he, moreover, soon acquires such countless negatives of his own famdy, and his own and his friend's dogs, that he is led to seek for other subjects wilder afield. He has, we will suppose, secured a tourist's set, very light and neatly packed in a hand case, together with a folding stand. With this he sallies forth; and varied and ambitious are his first ideas of landscape taking, especially when, as is often the case, he proceeds to do a landscape at the very first outset of his career.

The advice books generally suggest a first commencement being made upon some stationary object—such as a plaster bust, or a house, or something of a similarly motionless character. For my part, the very first photograph I attempted the early morning after I had brought my set home was a group consisting of five persons, a tricycle, and two dogs. I had passed the previous evening in reading up most carefully all that had to be done; and the night hours were largely filled with dreams of most striking pictures of phenomenal appearance and beauty. As soon as the group could be mustered in the morning they were marshalled on the lawn; but it was noticeable that upon the faces of all present—except that, perhaps, of the operator, who was a shade nervous—there were displayed looks, expressive of amused doubt, which further tended to the discomfiture of the embryo photographic artist. He, however, with due gravity, continued the operations as laid down in the manual, and finally exposed the plate. All the family accompanied him into the cellar, where the ruby lamp was lighted in readiness, and watched the process of flooding the plate with the ready-made developer with unflagging interest. Not that anything of a special nature was expected, but all seemed to be possessed of a vague curiosity to see what particular shape disaster would assume, and what sort of a fantastic affair would be evolved. When somebody's collar made its appearance as a black strip on the negative there was a chorus of "ah's!" but as detail after detail showed itself, and a fairly-satisfactory negative was produced, astonishment, mingled with some small respect for the operator, became manifest. In the presence of the leading fact that, after all, a picture had been produced, minor defects were passed lightly over, and there was a general agreement that we had succeeded in getting a good photograph—considering. While arranging the group it was decided that it would look nice to have the larger dog, a deerhound, gazing up affectionately into its mistress's face; and to this end the dog was spoken to, and coaxed, and pushed, until it did eventually pose itself in the required attitude. During the exposure, however, while all were casting the stony glare into space that people seem to think essential while being photographed, the dog had moved, and all the time had been carefully waving its bushy tail to and fro—the result being that in the resulting print, the whole dog presented the general appearance of a bundle of tow, no feature or limb of any kind being distinguishable; while the misguided animal had apparently discovered something upon the ground that required close examination. The other dog, a white one, was presented with three legs and a sort of pillowcase, and two distinct faces; but, nevertheless, it was tacitly understood that the effort was a great success, and foreboded great things to come.

In the same way the tyro, on his first expedition, instead of being content with one church, or a house, or one or two trees, for his first photograph away from home, sets himself to work to think which of all the views he remembers is the grandest, and probably hies himself and his camera to some high hill, or other point of vantage, and straightway proceeds to try to produce a landscape—upon his small plate—extending as far as the eye can reach, and the great probability is that he will be disgusted to find, instead of a similitude of one of the "Views by Frith," he has only about the first hundred yards, with, perhaps, a tree or two in focus, while their leaves and branches are misty, owing to the motion caused by the wind, while the cow in the field a-quarter of a mile off is rendered like a speck of dust.

In nothing so much as photography does wisdom come from experience, and the tyro soon learns to moderate his aspirations, and to confine his efforts to more practicable subjects until he gains more skill in the manipulation of his lens and his chemicals.

To the tourist the camera is a most interesting adjunct, as by its aid he can secure an ever-living view of each place of interest; and when he returns home, instead of seeking to laboriously describe in words the sights he has seen, all he need do is to proceed into the darkness of his cellar, or dark room, and develope his negatives, and then scatter his prints broadcast among inquiring friends.

During a tricycle tour in England and in Normandy and Brittany last year, the present writer took something like fifty or sixty views of different places and scenes of interest. Most of these turned out fairly well—although he was then but in the first months of his novitiate—and, therefore, it can readily be understood, that the art is not difficult of acquirement. One of these views was an *impromptu* picture of his *compagnon du voyage* fast asleep in bed at nine o'clock in the morning, when the breakfast bell was ringing and the amateur photographer had been out for a couple of hours in the early sunshine, and had been luxuriously bathing in the sea in St. Aubyn's Bay, Jersey. This picture is an everlasting memento of a lazy man, and is duly labelled as such.

The whole of the apparatus, stand and six plates included, only weighs five pounds eight ounces, so that there is no difficulty in transport.

The chemicals needed are usually simple to manage and do not soil the hands or clothes, and there is really little to stand as a set-off against the pleasures and advantages of the practice of amateur photography in its modern form.

SIGMA SMITH.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
August 12	Bolton Club	The Studio, Chancery-lane.
" 13	Bury	Temperance Hall.
" 13	Photographic Club	Anderton's Hotel, Fleet-street.
" 14	London and Provincial	Masons' Hall, Basinghall-street.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society, held on the 31st ult., the chair was occupied by Mr. W. E. Debenham.

Mr. A. COWAN showed an appliance intended to be placed between the lenses of a combination, to act as exposure shutter and as diaphragm. It consisted of two thin plates of ebonite, working close to each other and in opposite directions. In one position they left no opening, but upon being simultaneously moved in opposite directions they showed a square opening, the size of which depended upon the amount of motion given to these ebonite plates. A brass stop furnished with a tightening screw served to fix the limit of motion of the plates, and, consequently, the size of the aperture. A scale on one of the plates was marked to indicate, for each particular lens to be used, the place at which the stop-screw should be fixed to give a particular length of exposure, reckoned on the universal system.

The CHAIRMAN thought that the idea was very ingenious, but it was to be regretted that the form thus necessarily given to the diaphragm was square instead of circular.

A MEMBER suggested that an apparatus on a somewhat similar principle would make a good dissolver for the lantern, the slide being changed at the moment of complete closure.

Mr. COWAN had had that in view when constructing the slide.

Mr. W. COLES showed a print on one of the opal plates distributed by Mr. Ashman at the previous meeting. The print was of a deep rich colour. He (Mr. Coles) remarked that it had fixed out a great deal, and thought that it printed slower than paper.

Mr. W. H. PRESTWICH was of opinion that opal plates printed quicker than paper.

Mr. W. COBB showed a roll of paper especially made for packing purposes. It was rolled into flutes or grooves which, it was remarked, would serve as grooving for negative boxes. The paper itself resembled brown paper, but thicker, and was manufactured, as stated, from clay and straw. Mr. Cobb also showed 12 × 10 prints from an instantaneous negative of the procession on its way to the Hyde Park demonstration.

Mr. Coles inquired whether anyone present had had any experience with tissue paper as a covering for the glass roof and sides of the studio. He had been informed that when used on the sides the lights in the eyes of the sitters were made much too large.

Mr. Cobb said that the desirability of such a covering must depend on local circumstances.

A Member considered that tissue paper was scarcely as good as ground glass.

Mr. Cowan knew of two studios entirely glazed with ground glass, and no ill effect was complained of.

The Chairman was aware of a studio at an establishment of the highest class which was entirely covered with ground glass. For himself he had the roof glazed with a glass resembling that known as Hartley's rolled, but much whiter. It was not made in England, but came from St. Gobain, in France.

Mr. S. C. Salmon was elected a member.

MANCHESTER PHOTOGRAPHIC SOCIETY.

We are requested to state, in reference to the meeting of this Society already announced to take place on Wednesday next, the 13th inst., at Kirkstall Abbey, that if not less than ten persons give in their names steps will be taken to obtain a reduced rate of travelling charges, which will be about one single fare and a fourth for the double journey; but unless a sufficient number of names be given in to the leader (Mr. J. S. Pollitt) not later than Monday next, the 11th inst., no arrangements can be made for a reduced railway fare, and gentlemen going to the station on the morning of the 13th without having given previous notice will be expected to obtain their own tickets and pay the full ordinary fare. The train leaves the new Exchange station at 9 a.m.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The ordinary meeting of this Society was held on Thursday, 31st ult., at Llangollen, under the presidency of Dr. Kenyon.

Mr. H. Pedder was elected a member of the Association.

The day was a favourable one for photography, and, although the meeting was very scantily attended, good negatives were secured at Ruabon, Vale Crucis Abbey, and at Berwyn. A most enjoyable outing was experienced by those who were present.

AMATEUR PHOTOGRAPHIC ASSOCIATION OF VICTORIA.

The above Association celebrated its first anniversary by holding an exhibition on Monday, the 23rd June last.

The Association was formed on the 18th June, 1883, on which occasion nineteen members were enrolled. There are now forty-three names on the Society's register, and fresh nominations are received almost every month. The meetings have in general been well attended, and practical demonstrations of the leading photographic processes have been given from time to time and experiments conducted. This was the first amateur association formed in any of the Australian colonies or New Zealand, having been in existence since June of last year, although the Auckland Photographic Association received the credit of having beaten Australia, so far as priority was concerned; this, however, it will be seen, is not the case.

The exhibition was held in the Hall of the Royal Society of Victoria, in Melbourne, and included every description of photographic work. There was a very large attendance of visitors, the exhibition having proved a greater success than its promoters had ventured to anticipate. The greater part of the work shown was excellent; and, in addition to the stock apparatus, there were several novel inventions of the members, in the way of cameras, changing-boxes, and other apparatus. Some of the members have taken up the manufacture of gelatine plates, and have met with great success, which was shown by the abundant good work which they exhibited. Among the specialities shown were two or three professional exhibits.

Mr. Ludovico Hart, well known in English and French photographic circles, showed an exceedingly-interesting and well-executed set of photo-mechanical prints of all kinds. (Mr. Hart was formerly Superintendent of the Photo-mechanical Printing Department of the New South Wales Government in Sydney, as well as Lecturer on Photography at the Sydney Technical College.) The same gentleman also delivered an address at the exhibition on the *Rise and Progress of Photography*, tracing the art from the earliest period down to the present time, and detailing the difficulties which stood in the way of the early discoverers and pioneers.

The President of the Association delivered the opening address, and the exhibition closed with the display of a set of transparencies in the lantern, these being wholly the work of members.

Messrs. J. W. Lindt and Co., Nettleton, R. L. J. Ellery (Government Astronomer), and John Noone (Government Photographer), were well represented. Mr. Ellery sent several photographs of the moon and fixed stars, taken by the great Melbourne equatorial telescope, which was manufactured to the order of the Victorian Government, some years ago, by Mr. Howard Grubb, of Dublin. These would have formed objects of interest at any exhibition—direct photographs of the moon about eight inches in diameter, as well as several enlargements, being amongst them.

The work shown by Mr. John Noone was confined to copies of line drawings and engravings. Many improvements in the process of obtaining these specimens, as well as in photolithography generally, were the discoveries of Mr. Osborne, Mr. Noone's predecessor in the Department of Crown Lands, Melbourne. Papers of Mr. Osborne's were read at the meetings of the English societies twenty years since.

The Association meets on the first Monday in each month, at the Royal Society's Hall, Melbourne, and the members will always be pleased to see any photographers (amateur or professional) from the United Kingdom who may happen to visit Melbourne, and the President (Dr. Browning), the Secretary (Mr. J. H. Harvey), or any other member will be glad to take such visitors by the hand, and pilot them to the many pretty spots worth photographing which are to be found in and near Melbourne and the suburbs.

Correspondence.

August Meeting of the Photographic Society of France.—Eliminating Grease from Gelatine.—To Preserve Sensitive Albumenised Paper.—Presentation of Anatomic Proofs.—An Instantaneous Shutter, by M. Braun.—Another Rapid Shutter, by M. Davids.—M. Audra on the Keeping of Concentrated Solutions of Pyrogallic Acid.—Presentation by Professor Stebbing of Mr. McKellen's Portable Camera.—Vacation of the Society.

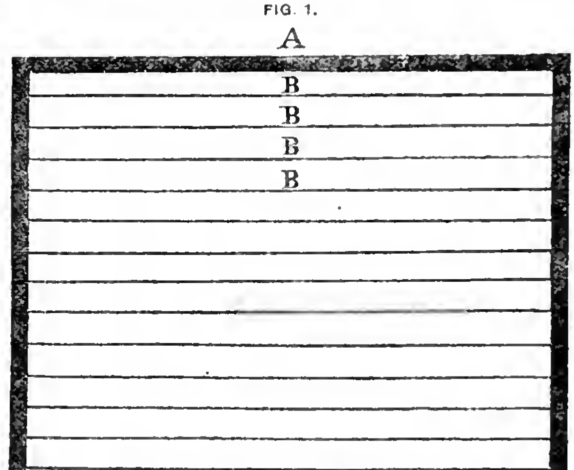
The usual monthly meeting of the Photographic Society of France was held on Friday evening last, the 1st instant,—M. Davanne in the chair.

In reading extracts from the photographic journals the Secretary drew attention to a plan for eliminating grease from gelatine, proposed by Herr Vogel, which, if it were true, is simplicity itself. It consists in merely washing the strips of gelatine in one or two changes of distilled water. An important discussion took place, and the power of distilled water to eliminate grease from gelatine was denied.

I informed my colleagues that I had always washed my gelatine before using it, but the washing was ineffectual when grease was present. I stated my opinion to be that grease was hardly ever equally distributed throughout the whole body of the gelatine, but only upon the surface of the sheets—the cause of which we must seek in its manufacture.

The gelatine, when hot, is received into a square wooden box or mould, the bottom of which is a little smaller than the top. When the gelatine has set the box is turned "topsy-turvy," the lump or loaf of gelatine falls out, and is then taken to a machine which carries the block of gelatine and forces it, as it were, through a frame of knives, which cuts it up into slices. Girls then take these slices and lay them upon network frames to dry. The frame of knives is composed of an

FIG. 1.



A, iron frame; B, &c., thin steel bands, like watch springs.

iron frame in which are fixed from ten to twenty watch springs according to the thickness of gelatine required (*fig.* 1). When very thin slices are desired the difficulty of cutting is at its maximum. It is here that the workman, in order to facilitate his task, greases the thin steel blades of his cutting-frame. This was of very little consequence before the gelatino-bromide process came into favour. A manufacturer informed me that this greasing was only prohibited for photographic gelatine, but he could not guarantee that it was not done "on the sly" by the workmen.

To sum up: I preferred thick gelatine when the quality was the same, and have found the idea given by M. Scola to be the best cure for greasy gelatine. He proposes to wash the gelatine in pure benzoline before using it. I have tried this system and found it good. Only pure benzoline must be used. After having been employed several times for the same purpose it is easily distilled, and so used over and over again.

A Member proposed a mixture of benzoline and alcohol—

Benzoline	....	1,000 parts.
Alcohol	....	250 ,,

A question arose as to how sensitive positive albumenised paper could be kept white for a long period, and the following was proposed :—Float the albumenised paper upon the following solution :—

Distilled water	....	1,000 parts.
Nitrate of silver	....	150 ,,

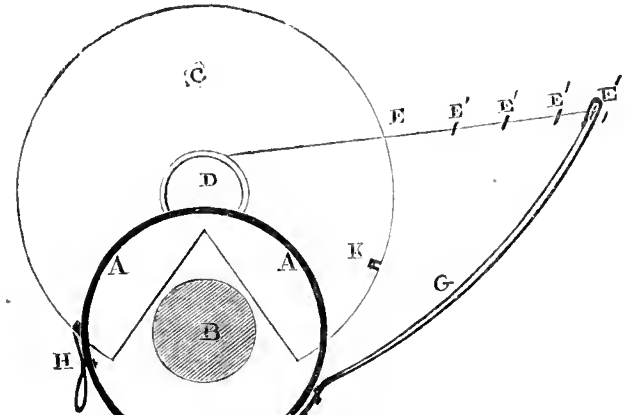
Allow it to remain from four to five minutes, then hang it up to drain. When the last drop has fallen off float the back of it upon a bath composed of citric and oxalic acids. The paper will remain white for a long time.

Another formula highly spoken of by many in the profession is simply to add to the positive bath as much nitrate of magnesia as of nitrate of silver. This addition, it is said, keeps the paper white for several months. If the back of the paper be floated upon water slightly acidulated with hydrochloric acid the whites will remain much purer.

M. Pinard presented some proofs of anatomical work and an oil painting of a surgical operation. A carbon transfer was made and laid upon a prepared canvas; the canvas was thoroughly cleaned by ox-gall, and then a solution of gelatine poured over it. This was found sufficient to make the carbon transfer adhere to the canvas. A painter then put on the required colours.

M. Andra, in the name of M. Braun, of Angoulême, presented a new instantaneous shutter. The shutter is formed by a revolving metallic disc out of which a segment has been taken. This disc is placed in the centre of the diaphragms, in order to obtain the greatest rapidity combined with the least possible distance to travel. On the axis to which this circular disc is fixed is a small wheel, to which is attached a piece of string, and when the disc is turned round for the exposure the string is wound round the wheel. If the string be

FIG. 2.



A A A, lens; B, aperture of lens; C, metallic disc; D, wheel on the axis; E, cord or string; E' E' E' E', knots in string; G, steel spring; H, catch; K, socket for catch.

pulled, naturally the disc will revolve back to its former position so much the more quickly the more violently the string is pulled. M. Braun has replaced the hand by a steel spring attached to the drum of the lens (*fig. 2*). By shortening or lengthening the string more or less rapid exposures may be obtained.

I think it was said that this shutter was constructed for M. Braun by Mr. Dallmeyer, of London. If so, the model can be seen there. I think with a little change this shutter will become the simplest and the best in the market. I should propose to change the string and spring with which the motion is given for a true watch spring on the axis, which could be wound up more or less according to requirements. M. Braun has thus brought out a very simple and workable instrument—an instrument which will remain when all others which have not for their basis the central position of the diaphragms will be, if not lost to memory, at least discarded from daily use.

M. David's shutter was presented, but it was found that it had been brought to our notice years ago under another name. It consists of a circular tube placed in the centre of, and at right angles with, the lens. This lens, or drum, has two holes in its side. When it revolves, and the two holes are in conjunction, the light passes through the lens, and from thence upon the sensitive plate. The drum continuing its course then presents a dark side to the opening of the lens, and the light is cut off.

M. Berge presented a series of calculations upon the true size of the aperture of photographic lenses. These tables, if found to be of value, will be published.

M. Andra informed the members that he had succeeded in keeping concentrated solutions of pyrogallic acid by the following means :—A solution of twelve per cent. of sulphite of soda is made; then another solution containing one-tenth of sulphuric acid is added. Eight parts of pyrogallic acid is now put in, which brings the strength to one gramme of pyrogallic acid for fifteen c.c. of water.

I had the honour to present Mr. McKellen's camera and dark slide. The lightness of the camera was specially remarked. The turn-table "dodge" was admired; but the dark slide obtained the most attention. The idea is very good, but a doubt was expressed as to its practical results, seeing the great difficulty of keeping rapid gelatino-bromide of silver plates from light during their changing in a simple bag.

The President said that if the maker had made a turntable for the bellows, so as to have had the camera of the form of a parallelogram instead of a square a much lighter apparatus still could have been obtained.

The back and front being on the swinging principle, gained the approval of the members.

The Secretary then announced the summer vacation, and the meeting was dissolved. E. STEBBING, *Prof.*

25, *Rue des Apennins, Paris, August* 4, 1884.

LIGHTING THE STUDIO.

To the EDITORS.

GENTLEMEN,—Your valuable and practical suggestion of reflectors, arranged after the fashion of a Venetian blind, will doubtless attract much attention. I presume the reflectors are to be used inside the studio, and not, as in the case of Chappuis' daylight reflector, on the outside.

I consider it such a matter of importance that I would venture to suggest a little set of drawings illustrating the system.—I am, yours, &c.,

79, *Princes-street, Edinburgh, August* 1, 1884. E. DEBENHAM.

[We think that drawings are scarcely necessary to make this matter thoroughly understood. The Venetian blinds may be fixed either inside or outside the studio.—EDS.]

GAS BOTTLES.

To the EDITORS.

GENTLEMEN,—Some time ago, when using a gas bottle, exhibiting for the then Mayor of this town on a public occasion, I was much annoyed at not being able to get a proper light in the lantern and had to give up the entertainment. On examination I discovered that the bottle, which should have contained oxygen, was full of air instead.

On writing to the party who had "filled" the bottle he was honest enough to own that he had found his pump was out of order, and that, therefore, it had been compressing air. No doubt several others beside myself had suffered like inconvenience and annoyance. I have not used a bottle since, as I see no reason why similar misfortunes may not very easily occur.

Query: suppose a bottle is being filled with hydrogen, and, through a leakage in the valves or other part of the machine, air is also pumped in, what would be the consequence?—I am, yours, &c., B. BOOTHROYD.

Southport, July 30, 1884.

PHOTOGRAPHY AND ART.

To the EDITORS.

GENTLEMEN,—If you will not take it amiss, I should like to make a remark or two in reply to your notice of my "mid-air" photographs—the *Flying Cupid*, the *Mercury*, and the *Curfew*—which you were kind enough to publish in No. 1,261 of the Journal.

After some very laudatory remarks, which I feel are not deserved, you state that the "cleverness" (as you were pleased to call it) displayed in the production of these pictures "belongs rather to the stage-carpenter than to the artist." Now, as far as this concerns my individual efforts I have nothing to say; but, if by that remark you imply that such work is at least not legitimate work for the art-loving photographer, it seems to me to merit some reply.

Photography has always been hampered by rigid laws and hostile agencies beyond the control of its devotees, to an extent unknown and altogether unappreciated by the complaisant artist at the easel. The camera artist must of necessity work between set limits—limits prescribed by the laws of optics, of chemistry, of human unsteadiness, &c. Whenever he goes outside of the strict lines so marked out, he attempts the impossible and fails to produce good results. Conceding this, why, *why* should not the art photographer explore the *entire* field of possibilities in his profession? And why would he not be more than justified in calling to his aid the best appliances, not only chemically and optically, but also mechanically, in the furtherance of unusually difficult work? What, after all, is the simple rigging necessary for a suspended position of the subject in the studio but an elaboration of the clumsy head-rest in daily use? And why should not the introduction of the instantaneous plate pave the way for photographic art—effects *formerly beyond the power of the photographer*, owing to the too great slowness of the wet plate?

No; it certainly is not a case of art-atrophy, but of progress, when the camera-worker calls to his aid, in the production of hitherto unattainable results, not only more sensitive chemicals than heretofore in vogue, but also the devices of the stage carpenter or machinist.

I consider photography an art worth living for, and to achieve legitimate and novel results under its banner, especially in life-work, I would subordinate to it the teachings, the applications, the clevernesses of all other known arts; and will not the entire brotherhood agree with me when I say that, if adventitious aid must be used, it is very much preferable to exercise the "cleverness of the stage-carpenter" rather than the methods employed by our best baby-photographers, which suggest the cleverness of the mountebank, the acrobat, and even of the circus clown?—I am, yours, &c., 949, *Broadway, New York.* B. J. FALK.

Notes and Queries.

ARGOSY wishes to be informed whether it is not incorrect and in bad taste for a photographer to print a portrait of a fair lady with auburn hair in such a manner as to represent her hair as being very dark.——To this we reply that it is both incorrect and in bad taste to do so.

"Is a portrait not better when taken by means of a lens very closely stopped down than when a large aperture is employed with the same lens?—A. T. G."——Answer: Not necessarily so; for, on the contrary, it may be said that the larger the aperture the greater the degree of pluck and vigour in the portrait caused, *inter alia*, by some parts being better defined than others.

"IRON" says:—"Could you kindly inform me what would turn ferricprussiate paper black after it has been fixed and washed (when it is blue)? I have tried a weak solution of ammonia, which only turned it a deeper blue, and oxalate of potash, the same as used in iron development, but the picture simply disappeared."——We reply that no reliable toning formula for the conversion of blue into black pictures has yet been published.

G. B. T. inquires:—"If I render a photograph transparent and colour it from behind do I infringe any patent?"——In reply: Innumerable patents have been taken out for doing what is here proposed; but as it was published and given freely to the world long before the first patent was taken out the method may, of course, be practised by anyone who chooses without any hindrance. It has been estimated that more patents have been taken out, in succession, for this method of colouring photographs than for any other invention, or so-called invention, ever brought before the public.

"I HAVE been troubled of late with blistering of my prints. After I have toned and fixed them blisters appear more or less all over the print. They are about the size of a pinhead or larger. When dry they still show, or where they are the spots are a little darker. Any remedy will be thankfully received by S. J. B."——In reply: Let our correspondent try the following:—After fixing the prints transfer them directly to a moderately-strong solution of chloride of soda, and allow them to remain in it previous to placing them in the washing tank. If this do not prove a remedy let our correspondent write again, enclosing a sample of his paper.

MONA says:—"Kindly inform me in next Journal how to use Weston's burnisher. I have one, and every time I try to use it, although I clean it well, the cards always stick and the back is spoilt."——In reply: "Mona" must first of all see that the feed roller is made rough by being rubbed longitudinally with coarse emery cloth. He should next give the prints a slight application of a suitable lubricant, such as an alcoholic solution of Castile soap, and, having made the burnisher warm, he must then pass the prints through, not applying too great pressure. Under these circumstances they will not stick, nor will the back be damaged in any way.

THOS. DUGDALE, Jun.—This correspondent has a studio situated just as described in an article in our last number; that is to say, it is surrounded by high buildings in such a manner and to such an extent as to render it exceedingly difficult to take a portrait in which the top light is not greatly in excess. He is favourably impressed by the idea of Venetian blinds of silvered glass, and believes it will effect a perfect cure of his trouble. He wishes a further hint or two with regard to the dimensions and method of fixing them.——In reply: The wooden laths should be about five inches wide, the glass being of the same width, and let the distance of one lath from another be such as may be determined by a trial. The frame containing the laths may be erected either outside of the side windows or inside.

J. G. G. writes:—"1. How is it that central flare is caused by *some* lenses and not by others?—2. I am not yet aware that I possess strength in any special department of photography, but the subjects I prefer to go for are actual operations and old implements of manufactures. As I find that the largest percentage of the prizes, &c., are given for the largest pictures, I wish to know the *most generally useful* size of camera and lens for one who wishes to compete with some chance of success."——In reply: 1. Central flare mainly results from the position of the lenses as regards distance from each other.—2. If our correspondent will employ 12×10 plates, or even those one or two sizes larger, he will have a good chance of producing imposing-looking pictures, which will undoubtedly attract more attention than if they were of small dimensions.

W. says:—"I observed in your Journal of the 25th ult. a plan of intensifying gelatine plates by mercury and sulphite of soda approved of in one of your leading paragraphs. I have just tried it. I washed the plate very carefully, bleached it with bichloride of mercury, then washed carefully, and put it into a bath of sulphite of soda (saturated solution one ounce, water one ounce), and, after keeping it there for twenty minutes, no change appeared; so I again well washed it and placed it in the usual ammonia bath, when it became black. I may mention that I develope with the oxalate of iron developer. Can you give me any reason for my failure?"——In reply: This is so contrary to the experience of ourselves and friends as to lead to the surmise that the substance tried cannot have been sul*phite* of soda at all, but probably sul*phate*; or, if it has been sulphite originally, it has oxidised into sulphate.

"IN last week's Journal I notice your reply to a querist asking particulars respecting North Wales. I should also be glad to know what focus of lenses for covering whole plates would be the best to take to that district. In the articles *Where to Go with the Camera* places are described as being good for camera work, and this place and that place are mentioned as making charming views; but I have looked in vain to see the size of plate and focus of lens best adapted for taking the view. Unfortunately some amateurs possess only one lens, and when they get on the spot find they are unable to take the view. I think you will agree with me when I say that if, in the descriptions of places they will take a certain size of plate—say whole plate—and give the focus of the lenses used in the production of the best views, the writers would confer a benefit on amateurs working the district described.—JOHN T. LEES."——To this we reply that such addition to the description of places as is here suggested is really unnecessary; for if a photographer will provide himself with a very small equipment of lenses—one of which has a focus nearly equal to the length of the plate employed, and another somewhat longer in focus—he will be prepared for almost every emergency as regards included subject. This is not a matter of size of plate, but one of relation of foci of lenses to the plate, no matter what its dimensions may be.

PRIMULA writes:—"I am about to deliver a popular lecture on photography to the children and teachers of a Sunday school with which I am connected, and would feel greatly indebted if you inform me what light I should use in order to take a photograph from the life in the course of my lecture. Not having any experience of the lime light I would greatly prefer the employment of any other means of illuminating my sitter."——In reply: The best light for such a purpose as the one described is that emitted from magnesium. No preparation or gas bags are required. The metal is ignited and burns brilliantly. It may, however, be necessary, and it certainly will be desirable, to make ample provision for getting rid of the fumes emitted from the incandescent metal. "Primula" should make a careful and thorough rehearsal of the intended experiment previous to the evening on which he intends to lecture, and he will thus ascertain by personal experience the precise quantity of magnesium required to give light sufficient to impress an image on a gelatine plate. If from any cause our correspondent, from necessity or choice, cannot employ the magnesium light, he may obtain a light of great actinic power by the admixture of one part of sulphide of antimony and two parts of sulphur with six parts of nitrate of potash. These ingredients must be powdered separately when dry, and then thoroughly mixed. When ignited this gives a light of surpassing brilliancy.

Exchange Column.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

PHOTOGRAPHS REGISTERED.—

William Pankhurst Marsh, Norfolk Cottage, Bognor.—*Three Instantaneous Photographs of Esplanade and Sands at Bognor. Two Photographs of the Goodwood Racecourse.*

J. AND A. J. HOPKINS.—Received too late for this week.

F. WRIGHT.—The apparatus in question is not an article of commerce—at least in this country.

R. L. M.—No relative, so far as we know—certainly not what may be termed a very near relative, at anyrate.

J. G. G.—The gentleman you name uses plates nearer to twenty inches than of quarter-plate dimensions. For other replies see *Notes and Queries.*

E. H. D.—Your letter has been forwarded. We shall be most happy to meet you when you are in our neighbourhood.

T. H. S.—See in *Our Editorial Table* for notices of handbooks or manuals for beginners. We have no preference for, and never recommend any, special one.

A. Z. and NEMO.—These correspondents have not complied with our rule by enclosing their names and addresses; hence their queries remain unanswered.

K. F.—Any of the formulæ given in our ALMANAC for the last three or four years may be employed. You will, perhaps, get on better by employing a slow emulsion in your first experiments.

INQUIRENDO.—Several plans have been suggested for reducing over-printed pictures; but the best remedy in practice is to tear up the prints and make fresh ones. It is best and most satisfactory in the long run.

A. H. I.—There is no question that if the plate were not thoroughly washed the developing action would proceed, to some extent, while it was soaking in a small quantity of water, which might increase the intensity slightly.

G. HOLLINGSLY.—The advantage of trimming the prints prior to toning is that you economise gold. Bear in mind that if the dark edges remain they will, of course, be toned the same as the picture, and, possibly, consume more gold than the image.

P. S.—Unless you possess one of the graduated screens actually prepared by Mr. Warnerke for use with his sensitometer it is hopeless to attempt to draw any line of comparison between your own results and those of others. The mere possession of a phosphorescent tablet means nothing—if you made it yourself, perhaps less.

QUARTER-PLATE.—Any firm who makes a speciality of enlargements will do the work for you, but we doubt if they can supply the diagram in one piece; it would probably have to be joined. Would it not answer your purpose to project the image of the transparency, by means of a magic lantern, on to a screen and then trace it with crayons?

W. S.—The best plan of preventing the collodion plate drying during hot weather is to place a wet cloth at the bottom of the camera during the exposure. A somewhat thick collodion, made with a porous pyroxyline, will also help matters considerably, as such a collodion has less tendency to dry—or, at least, to produce stains—than one made with a horny sample.

FREUND.—The result is quite as it should be. The effect of adding barium nitrate to the ferrous sulphate is to bring about an interchange of elements, ferrous nitrate remaining in solution while insoluble barium sulphate is precipitated, and should be removed by filtration. Acidify with acetic acid, and employ in the usual manner. This developer was highly recommended at one time.

PUZZLED.—You are using a lens of far too short focus. Instead of replacing your seven-inch focus objective by one of five inches, you would have done better to have changed it for one of ten or twelve inches focus. Your argument that because the five-inch lens is a more powerful magnifier than the seven-inch it should render the object on a larger scale in the camera is based upon a complete misapprehension of the laws of optics.

A NOVICE IN PRINTING.—The "marbled stains" on the piece of paper enclosed arise from you having floated it upon the sensitising bath while it had a scum upon its surface. If, after floating a few pieces of paper, you allow the solution to stand in the dish, in a short time a scum forms upon the surface. This must always be removed by drawing a strip of blotting-paper over it; otherwise you will always be troubled with the markings.

CANARY.—1. The yellow precipitate you complain of is sulphur—the result of the decomposition of the sodium hyposulphite by the acid. Acid should never be added to the hypo.; it is, indeed, better to purposely render it *very slightly* alkaline.—2. The "new fixing agent," as you describe it—sodium thiosulphate—is only our old friend hypo. in a new garb. The correct modern name for the salt you know as sodium *hyposulphite* is sodium *thiosulphate*.

JAMES HENDERSON.—Your room will certainly be improved for portraiture if you increase the size of the side window as you propose; also, by the addition of a top light—say extending half way across the roof and the same length, or a little longer than that at the side. The cause of the heavy shadows in the portraits sent is that you have not managed what light you at present possess to the best advantage. Read the series of articles on *Portraiture for Amateurs*, which appeared in our volumes for 1882 83. These will afford you much useful information.

W. S.—The spots are by no means easy to be accounted for. If the mounts had been printed with bronze powder we should at once have attributed the spottiness to particles of the bronze on the front of the cards. However, this may still be the cause. Have you any mounts printed with bronze about your mounting room? or have any been passed through the rolling-press at the time these were rolled, through which particles of the powder might have adhered to the rollers, and so caused contamination? If not, the most likely suggestion is that there is something deleterious in the mountant you have employed.

FORRESTER.—1. There is no satisfactory method of reducing a negative which has been intensified with mercury.—2. The small spots are, in all probability, due to the negative being insufficiently washed after intensification; hence contact with the silver paper has caused the spots. The plan you have pursued in mercurial intensification will not, *per se*, produce spottiness; that is caused by the silver in the paper.—3. All things being equal, no difference should exist between the exposure of the two lenses. It may happen, however, that from a difference in the tint of the glass one instrument will be somewhat more rapid than the other.

J. G. LEWIS.—The "cut-out" appearance of the portraits is due to the background being placed too close to the figure. Arrange it so that it shall be three or four feet from the sitter and the effect will be far better. Never mind its being out of focus—all the better.

THE LATE MR. J. L. LANE.—We regret to have to announce the decease of this gentleman, so long identified with the manufacture of cameras and other photographic requisites. Although long a sufferer from illness, the deceased retained to the last the clearness of judgment and intellect which he always possessed in a remarkable degree. On the 19th ult. he was taken suddenly ill, and died on the 29th, "full of years and honours." The funeral took place at Norwood Cemetery on Tuesday last. We understand that the business will be carried on by his sons, under the style of "J. L. Lane and Sons." On the latter has for some time devolved the conduct of the business during the long illness of the senior Mr. Lane,

MOUNTING PRINTS ON MUSLIN. — At a recent meeting of the Rochester (New York) Photographic Society, Mr. J. M. Fox gave the following account of his method of mounting prints on cloth. He said:—"After trying many experiments in double mounting on muslin I have adopted the following method:—I prepare several yards of cloth at a time by sizing with starch, and always keep a roll of it on hand ready for use. While damp the cloth is stretched not too tightly on a frame and sized plentifully with warm starch paste made rather thin, and spread on evenly. Where large quantities of muslin are used perhaps tenter bars might be employed to advantage for stretching. When dry cloth is cut to the size required before mounting, allowance being made for the expansion of the prints, if the starch for mounting be used while warm (which I think is preferable), it should be as stiff as can be conveniently spread on the print, for the reason that it will expand the cloth less and dry quicker. From the moment the first print touches the cloth dispatch is important; therefore both prints are first pasted, one being laid aside ready to be picked up quickly. The first print is rubbed down with a hand-roller, which can be done more expeditiously than with the hands. When the second print is properly laid on the side there is less occasion for haste, and rubbing down by hand is preferable; because, although the roller does the work perfectly on the first print mounted, it is liable to leave air-bubbles in rolling down the second one. To avoid bubbles in the hand-rubbing the strokes should be towards the middle of the print, and not in every direction from the centre. When the mounting is completed the prints are placed between papers and covered immediately with several folds of cloth of sufficient weight to keep them in place. To facilitate drying they may be aired after an hour or two and placed between dry papers and again covered with the cloth."

METEOROLOGICAL REPORT.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1267. Vol. XXXI.—AUGUST 15, 1884.

ALBUMEN IN GELATINE EMULSIONS.

With regard to the persistent clotting which occurs when silver nitrate is added to even a thick solution of gelatine containing albumen, the result may be pretty safely laid down to the coagulation of the albumen, and not to the formation of albumenate of silver; that is to say, if albumen could be introduced into the emulsion in such a form that, while still capable of combining chemically with silver salts, it remained uncoagulable either by their action or by heat or alcohol, then the difficulty of obtaining an emulsion of silver albumenate would be removed.

There is no obvious reason why albumenate of silver should precipitate in a coarser state than bromide, chloride, or iodide; indeed, from the nature of the compound it would seem to offer the prospect of being more easily diffused in a condition of extreme fineness in a viscous solution than any of the inorganic silver compounds. We know, moreover, that albumen can be mixed with gelatine to form a clear solution so long as the temperature remains below a certain point; but immediately it is raised sufficiently high to cause coagulation, the objectionable want of homogeneity is produced. Hence we have been led to the conclusion that it is coagulation, *per se*, that has to be guarded against.

One of the first suggestions that presented itself was the formation of the albumenate separately, and its subsequent addition to the emulsion in alkaline solution; but this plan was at once rejected on trial. In fact, it soon became clear that, in order to preserve the conditions which are necessary to the preparation of a successful emulsion, there must be no complications arising from the presence of foreign matters. It was needful, therefore, to seek for some means of modifying the character of the albumen itself.

Few of our readers require to be told that albumen exists in the soluble and insoluble conditions. It exists in the former state naturally, but is changed to the latter by the application of heat, by the action of alcohol, and by a very large number of metallic salts and the mineral acids. This change is known as "coagulation," and upon it depends the chief value of albumen in its industrial application. For our purposes, however, we have to endeavour to avoid coagulation by altering the character of the albumen.

It is not needful to go into the whole chemistry of this interesting substance, nor to detail the remarkable series of reactions it exhibits under various conditions. We shall confine ourselves merely to one or two methods of treatment which seem to offer the chance of bending it to our purpose.

We have said that soluble albumen is converted to the insoluble form by heat and by the action of the mineral acids. These conditions may, however, be nearly exactly reversed. Thus, acetic, citric, tartaric, phosphoric, and most of the organic acids fail to produce any precipitate in dilute solutions of albumen; but if added to concentrated solutions the whole solidifies to a jelly, which may be freed from excess of acid by washing. This jelly possesses properties the reverse of ordinary albumen. It is solid in the cold, but becomes liquid when heated, and again sets into a jelly as it cools just as gelatine does. It is not coagulated by alcohol—indeed is partly soluble in that liquid—and it may be boiled without coagulation.

Unlike ordinary soluble albumen, however, this solution is precipitated by weak alkalies and by solutions of the neutral salts of the alkali metals. On the other hand, many of the metallic salts which coagulate soluble albumen fail to produce any precipitate with the warm solution of this jelly.

The non-coagulability of this substance by heat would seem to render it specially applicable for use in emulsions that have to be boiled, while the fact of its setting upon cooling forms another recommendation in its favour; still another is the circumstance that when once dried it becomes insoluble, so that films containing this altered albumen would be particularly hard and suitable for use in hot climates. But its easy decomposition by neutral and comparatively-inert salts renders it probable that its utility would be very limited in the ordinary methods of emulsification, as both the alkaline bromides and the nitrates produced by double decomposition would precipitate it in a more or less flocculent form, and most probably in such a state as to render the emulsion worthless. For these reasons we have not yet experimented with this curious substance, but mention it as being a possible means of employing albumen.

We have, however, obtained some tolerably satisfactory results with a similar preparation, though it would be premature to say much at this stage of our experiment. We may, however, venture to assert that it is extremely easy to make a gelatino-albumeno-emulsion in which the albumen may be present in almost any desired proportion in *chemical* combination with the silver salts—an advance on our previous experiments that we could scarcely have hoped to attain a short time back. We have as yet not had time to adjust the proportions of the various materials so as to make a good working formula, but we may hope to do so soon. Meanwhile, we give a general sketch of the *modus operandi* in order that those of our readers who choose to do so may take up this line of experiment.

If the white of an egg, just as it comes from the shell, be beaten and allowed to settle and then treated with a strong solution of caustic potash it is transformed into a tough, gelatinous mass, which may be broken up and washed in cold water until free from alkali. The proportion of alkali we have employed has been sixty grains of potassium hydrate (dissolved in two drachms of water) to each ounce of albumen. Add this gradually to the albumen, stirring very thoroughly, as, if added too rapidly, the gelatinous mass becomes so stiff and unmanageable as to cause considerable loss. Allow the action to continue for a-quarter of an hour, and then pour off the solution and wash rapidly in several changes of water; finally, break up the mass into small pieces, and wash in running water in a canvas bag for some hours.

The result at ordinary temperature is a firm, gelatinous substance closely resembling clear, swelled gelatine. If it be exposed to the temperature of boiling water, over a water bath, it slowly liquefies, and remains permanently liquid on cooling. The jelly may be dissolved in boiling alcohol, and from this solution it is again precipitated by ether, still retaining its original properties. Organic acids precipitate it in a form insoluble in water, either hot or cold, but soluble in excess of acid. With nitrate of silver it forms a fine, white precipitate—presumably silver albumenate—which darkens rapidly to a full black in sunshine.

If a certain proportion of this jelly be heated with gelatine until completely dissolved, the soluble haloids and, subsequently, the silver nitrate added, an emulsion is formed possessing all the smoothness of the finest gelatine emulsion, and possessing the additional property of darkening rapidly to a full, strong tint on direct exposure to light.

For the reasons we have given we make no attempt at stating a formula, but place the matter in our readers' hands ready for experiment.

In our article last week, page 497, twelfth line from the bottom, for "bromine absolver" *read* "bromine absorber."

VIGNETTING FRAMES.

A vignetting attachment to a printing-frame exhibited at the last meeting of the London and Provincial Photographic Association is believed to possess certain features which may render the details of its construction of value to some of our readers.

Its principle—that of universal adjustment—has been recognised for many years; not only so, but certain applications of the principle have formed subjects of patents, and have already elicited our encomiums on account of their ingenuity. In this special example of carrying out the principle the materials are of such a nature, and the workmanship so very easily effected, as to render its construction a matter which will fall within the powers of any one whose mechanical skill does not even extend beyond the rudimentary stage. This vignetter is, in its precise form, of American origin, and is stated to emanate from a photographer bearing the Chinese cognomen of "Singhi."

A light wooden frame is fashioned so as to fit over the printing-frame, much in the same way as a cap fits upon the hood of a lens, and with a similar degree of tightness. A little glue, aided by a few brads, suffices to keep the frame together. Attached to one side of this frame is a cover formed of a very thin, hard, brown millboard of about the thickness and consistency of a cardboard mount of good quality for cabinet portraits. It is highly calendered, and is known in the paper trade as "glazed board." A sheet of this forms the cover of the frame, to which it is attached by glue or, as in that which we examined, a half dozen small brass tacks. In this cover is an aperture of dimensions corresponding to that in the printing-frame, whether whole-plate, half-plate, or any other size. When, therefore, this framed cover is placed upon the printing-frame there is nothing to prevent the negative from being printed full out to the margin. But glued to each end, and on the face of the cover, is a strip of the same millboard one inch in width, having a slip underneath throughout half its breadth so as to provide accommodation for another sheet of board intended to slide underneath these guides, like the rising-front of a camera. This sliding sheet—the motion of which is across the frame—also has in it an aperture of the same dimensions as that in the fixed or foundation piece; and it, too, is fitted with strips like the other for the reception of still another sliding piece. In this case, however, they are placed in the longitudinal direction of the aperture—not across it, as in the previous one. Now, it will be obvious that if another sheet of millboard, containing an aperture, be made to slide in this latter piece, it will be possible by the two motions, longitudinal and transverse, to bring such aperture directly opposite any part of the negative. But the principle of universal application is carried still further. One of the longitudinal sliding pieces is fitted with guiding strips so as to permit of still smaller slides being employed, and these may contain oval, square, circular, or pear-shaped apertures, placed in any desirable position and of even the smallest dimensions.

When covered with tissue paper, or when printing in the shade without such covering, the vignetting of a figure is effected with the greatest accuracy. The adjustments are quickly made, and if the operator have not a mask of the precise form suited to the requirements of a particular portrait, one may be made by either cutting an aperture in a slip of paper and fixing it with gum to one of the cardboard slides, or by aid of a crayon stump and black chalk a Waymouth vignetting paper may be extemporised.

This is a convenient form of vignetting mask, introduced in the summer of 1872 by the late Mr. John D. Waymouth, of Nailsea, near Bristol, consisting of a sheet of thin and transparent paper printed black all over, except in the centre, in which is a clear aperture of one or other of the numerous forms employed in vignetting—this aperture having graduated edges to form the vignette. As the whole stock was, on the death of Mr. Waymouth, purchased by a gentleman in the south of London, there are no genuine Waymouth vignetting papers now to be had; but their preparation is not attended with any difficulty. It is only necessary to obtain a sheet of opaque paper of any kind, cut in it an aperture a little longer than the vignette desired, paste over it a small sheet of tissue paper, and with the crayon stump or a bit of black chalk to carry in the opacity gradually from the margin of the tissue-paper towards the centre, leaving a portion there quite clear. There being now no restriction, moral or legal, upon its manufacture or employment (although when first brought out twelve years ago Mr. Waymouth had his invention protected by a three years' registration), there is no reason why some enterprising lithographer should not manufacture these papers in this country as well as in the United States of America, where, we learn from contemporary transatlantic journals, one person at least manufactures and supplies them to the public. But all this is by the way, so we return to our vignetting-frame.

If the vignetting-frame be pushed closely down upon the printing-frame this action will ensure the vignetting-mask being situated at a definite distance from the negative. But it may happen that a still greater distance might be desirable, in order to obtain an enhanced degree of softness in the vignetting. This is secured by a method the simplicity of which will approve itself to everyone. A band of elastic tape, attached to the vignetting-frame at each end in such a manner as to pass round the printing-frame, secures both of these together, and by means of a square perforation near the ends of the former it is possible to insert between the two frames a square stick, the point of which is wedge-shaped for facility of entrance. This effects an increase of the distance between the vignette-mask and the negative to an extent equal to the thickness of the stick. By these means the vignetting may be either made gentle or abrupt.

GREASE IN GELATINE.

It is needless to say that workers in every branch of photography in which gelatine is concerned know quite well it is rarely that any two samples of this material can be procured commercially which are identical in their characteristics, although they may have been made by the same manufacturer—unless, indeed, which is seldom the case, they happen to be actually out of the same batch or making. These remarks, be it understood, do not apply with equal force to the better class of gelatines by English makers, for, as a rule, they are far more uniform in their character than are those of foreign makers.

Unfortunately, however, English gelatines are not so well adapted for many photographic purposes as are the better qualities of continental gelatines. The latter, generally speaking, are harder and less soluble than the former, which renders them far more suitable where toughness and insolubility is an absolute necessity, particularly at this season of the year. Apart from the want of uniformity in composition, foreign gelatines are liable to produce certain spots and pits in the film, which are far too familiar to dry-plate workers. It frequently happens that those samples which, in other respects, may be most suitable are those which give the greatest amount of trouble with regard to pits and spots. It may not be so generally known that pits, like those on dry plates, are always formed in the film, if a similar sample of gelatine be used in the collotype process; and here they cause spots on the impressions when taken from the plates. If a pitting sample of gelatine be employed in the carbon process—either for transfer paper or tissue—it gives equal trouble; for what in a film formed in a horizontal position (as on a dry plate or a collotype plate) would be a pit becomes what is technically called a "bleb," formed thus:—As the paper leaves the solution the pit forms, and, as the paper is for a short time in a vertical position, the pit elongates and causes a tear-shaped mark of thinner coating.

Various theories, as all our readers are aware, have been promulgated to account for these peculiarities—one of which is, that they have their origin in grease. But the grease theory will not account for all the spots met with. Evidently there are spots and spots, and, until gelatine makers will take photographers more into their confidence, and let them into a few of their "trade secrets," we fear we shall still be troubled with uncertainty, as the manufacturers do not thoroughly understand the photographer's requisites, even if they *could* meet them. Incidentally we may here mention that some of the worst samples of spotty gelatine we have had to deal with were labelled as being specially prepared for photographic purposes.

There is no question whatever that for every purpose, photographic or otherwise, for which gelatine is employed grease must always be more or less an evil. The questions very naturally suggest themselves as to how the grease is introduced into the gelatine, and if it be not possible to eliminate it. Grease may, and probably does, exist in two forms: one in which it is incorporated with the gelatine in its manufacture—possibly from small particles of fat on the hides, bones, or sinews from which it is made; the other in which it exists on the surface only, acquired after the gelatine has been made—in all probability from the nets or wires upon which it is dried being slightly greased, to prevent its adhering, or maybe from the machinery used in cutting it into flakes or shreds.

The elimination of grease from gelatine is by no means the easy matter that it may appear, particularly when it is incorporated with the gelatine itself. One of the plans suggested—and it is one that might be supposed would answer—is to add to the gelatine ammonia or other alkali in small quantity, with a view of converting the grease into soap, and so render it innocuous. On putting this suggestion to the trial of practice it has proved to be ineffectual, as it fails entirely to eliminate the greasy matter when it is incorporated with the gelatine, though it may answer to an extent when it is on the surface only. Another plan which has been suggested is to precipitate the gelatine from its solution, wash the precipitate, and then redissolve. Theoretically this plan should answer, but in practice it does not produce satisfactory results. In one or two experiments with this method we have been successful, but in others we have failed completely. In fact, one sample thus treated proved to be, with regard to pits, about the worst we have ever met with.

At the last meeting of the Photographic Society of France the subject of the elimination of grease from gelatine formed a topic for discussion. This arose out of a suggestion of Herr Vogel's to wash the gelatine in two or three changes of distilled water. Why this treatment should remove grease we fail to see, and, at the meeting referred to, the fact that it did so was denied. If the grease exist only on the surface it can, however, generally be completely removed by washing the gelatine with either ether or benzole. Several samples that we have experimented upon, which pitted badly before, after this treatment gave a film as free from spots or pits as could be desired. But this plan fails entirely when the grease is diffused through the substance of the gelatine.

The only plan which has proved effectual in our hands under all circumstances is that of clarifying the gelatine with albumen, as described in our columns quite recently. With it we have made a great number of experiments, and we have never met with a single failure. But whether it will answer under every condition, in the presence of the vagaries of gelatine, it is too much to hazard an opinion. Now, having to clarify or otherwise treat a gelatine before it can be successfully employed is undoubtedly troublesome and inconvenient. In practice it is far more convenient and economical in the long run to discard an unsuitable gelatine than to attempt to doctor it before it can be used. There are samples to be met with which do not require any such treatment; but, as we have said before, they cannot be relied upon at the time of purchasing.

Unfortunately, at present we are as much at the mercy of the gelatine manufacturers as we are of the photographic paper-makers, and must, perforce, be content with what they supply and make the best of it. As a practical hint, we may say the best plan of obtaining a reliable article is to procure a small quantity of different samples, try them, and, when one is found which works satisfactorily, to secure a sufficient quantity to last a considerable time, as gelatine does not deteriorate by keeping, provided it be kept in a dry place. This plan, if it be adopted, will save much trouble and anxiety, and, it may be mentioned, is one frequently pursued by large consumers. One firm we are aware of, who manufacture dry plates, found, a short time back, an exceptionally good sample for their purpose in the market, and secured the whole making, amounting to many hundredweights, congratulating themselves by so doing that for a considerable time to come they would be free from all anxiety—at least with regard to the character of their gelatine.

PHOTOGRAPHY AND PHYSIOLOGICAL OPTICS.

Photographers do not differ from others in wishing to possess the *mens sana, in corpore sano;* but, though doubtless all of them thoroughly believe in their enjoyment of the former, the possession of the latter, so far as regards that organ alone which now interests us, the eye, is by no means common. We pointed out last week how desirable it was for every photographer, working as he does under trying conditions of light, to make use of spectacles or adopt other optical assistance rather than strain his eyes in the slightest degree in endeavouring to discern details of his work which are rather beyond his ocular powers.

With regard to the actual capabilities of the eye: it may be interesting to note that the results of a large number of examinations show that a minority of persons possess healthy, normal eyes. Thus, twenty-eight per cent. possess the peculiarity described by us last week as existing in one of our contributors, though not to the same extent—we refer to the unequal power of the eyes; and seven per cent. find the reading of the small type termed "diamond" beyond their capacity altogether, thus clearly showing that one man out of every fourteen could not focus accurately without some kind of lens to assist him.

It has been roundly asserted of late years that the strain put upon the eyes of school children and students is causing a gradual deterioration in the present generation; but the statistics we have referred to show that such is not really the case, and that, on the contrary, from the age of ten upwards to forty a slight improvement takes place. The Rev. T. K. Preston, of Marlborough College, has made a large number of examinations of the boys and found that the eyes of more than one-half of them were astigmatic to a greater or less extent, and that this particular quality increased with age. It is evident that anyone whose eyes were so defective could easily arrive at a false judgment as to the qualities of a lens under examination unless certain precautions were taken.

This part of the subject is too large to enter upon fully in our pages, though we may be induced at some future time to give a few examples or diagrams which would enable anyone to test for himself the exact power of his own eyes. Meanwhile we advise those of our readers who should visit the "Healtheries" to find out the Anthropometric Laboratory, where will be found every convenience for testing eyes accurately and scientifically, and with skilled assistance to aid. Several hundreds of examinations have already been made, constituting a valuable addition to the accumulated store of facts, in addition to satisfying a laudable curiosity—or, perhaps, we should say a legitimate desire for information.

Among other data the kind of colour-blindness and the degree to which the visitor's defect extends may be ascertained without difficulty, this peculiarity especially being one not readily discriminated without special means at hand. It exists in many persons, some of whom are known to have been quite ignorant of it almost through life. We could instance the case of a colour-blind gentleman who was educated as an artist, passed through school and college in ignorance of his defect, and did not discover it till he had arrived at manhood. We could point out another gentleman who is so entirely colour-blind that, on a recent occasion, he could not discover any difference between the colour of blood and a piece of blue wrapping-paper. There are individuals who have a generally imperfect power, of greater or less extent, of discriminating colours, and others whose defect of power lies in certain directions only. Thus, there is green blindness, red blindness, and violet blindness—each of which naturally is to be perceived, not alone in the examination of objects so coloured, but in all hues and tints of which it forms one of the constituent elements.

The actual percentage of colour-blind male subjects out of over fourteen thousand examined, all classes mixed, is 4·16—that is, about one person in every twenty-five is colour-blind; but of a smaller number of females the percentage was ·4—that is, one in two hundred and fifty. Members of the Society of Friends had the largest proportion of colour-blind, 5·9 being the proportion.

With all these facts before us it becomes matter beyond doubt when the question of dark-room illumination and the visibility under different lights of certain tests—printed matter, and soforth—is being discussed, that there is every probability that some of those who take part in it are deficient in the colour sense to a certain extent, and so are incompetent to give an opinion of any value to photographers whose eyesight is normal. Probably, if the most vigorous tests possible were carried out, it might be found that very few people indeed had eyes perfectly perceptive of all colours. We ourselves, at the moment of writing, while feeling that we possess the power of colour perception to an acute degree, are conscious of a distinct difference in the quality of light as perceived by the right or left eye; but to be able to note such minute differences requires both the power to receive and the training to observe such *nuances*.

As we have said, we recommend everyone who possibly can to pay a visit to the Anthropometrical Laboratory at the Health Exhibition to learn for himself. For those who cannot we strongly recommend the purchase and perusal of a little work lately published by Churchill, embodying the recommendations of the Anthropometrical Commission of the British Association, altered and improved in this, the second edition, by the editor, Mr. Chas. Roberts, F.R.C.S. The work is entitled *The Detection of Colour-Blindness and Imperfect Vision*, and it contains a variety of carefully printed diagrams and letters for enabling the qualities of long and short sight, acuteness of vision, astigmatism, &c., to be ascertained. At the end of the book also, worked on to the last page, will be found a set of coloured Berlin wools, arranged in series upon a given plan, so that the degree of colour-blindness and its kind can be readily tested. When, finally, we say that the publishing price is only five shillings, our readers will not think we are recommending a large expenditure to satisfy the gratification of a desire for knowledge, whether it be termed laudable curiosity or thirst for information.

The ample programme issued thus far in advance of the opening of the International Inventions Exhibition, which is to form the third of the series inaugurated last year with the "Fisheries," and continued this year by the "Healtheries," gives promise that it will be at least as interesting and popular as its predecessors. In photography especially, which is honoured by having a group to itself, we have particular reason to be satisfied with the arrangements, and we have little doubt that there will be a full response. One noticeable feature is the total absence of the almost antediluvian notions which generally mark the official arrangements in connection with photography at such exhibitions. Here all is fresh and modern, and, as a matter of course, useful.

The editor of the *American Monthly Microscopical Journal* gives a very fully-detailed method for treating alcoholic solution of shellac to get rid of the well-known thick opaque magma which, by the ordinary method of treatment, is so difficult to filter out. We have often pointed out that shellac contains certain matters not entirely soluble in spirit, and that the part which is soluble is not simply one homogeneous substance, but is a mixture. The important question arises—"Does the process of freeing the solution from its insoluble accompaniment in any way interfere with soluble constituents?" Experience alone can determine, and it would be advisable to put the matter to the test. The instructions are as follow:—To prepare the cement obtain from the paint shop a quantity of shellac and good varnish, or prepare it by dissolving common shellac in alcohol. It is well to use five or six ounces of the varnish, as there will be considerable shrinkage of volume during the process. Place the varnish in a bottle, which should not be more than two-thirds full, and add to it about a quarter of its volume of naphtha or petroleum spirit. In our recent operations we used gasoline, which happened to be at hand, with satisfactory results. Put in the cork and shake well in order to thoroughly mix the two liquids. Let the mixture stand a few minutes, and shake it again, repeating the operation two or three times. Then let the bottle stand undisturbed for twelve hours, or as much longer as convenient. The naphtha will be found in a layer above the shellac containing the flocculent matter, which, being insoluble in cold water, renders the ordinary solutions of shellac turbid, while the alcoholic solution beneath will be perfectly clear. With the aid of a syphon, extemporised by means of a piece of rubber or glass tube, the clear shellac may be drawn off from beneath the naphtha.

There seems to be a probability that the metal iridium, which, from its peculiar properties of extreme hardness and power of resistance to all chemical agents, would be of great value for many technical purposes, may be rendered capable of being worked with no very great difficulty. Mr. Holland discovered, some time since, when engaged in working the stylographic pen, that when the metal was heated to a white heat and exposed to the action of phosphorous it could be brought to a state of complete fusion, so that it might be cast into any desired shape. There are many difficulties in the way of its extended use, not the least of these being that of obtaining it in quantity. It is said, however, to be stored in the vaults of the Imperial Mint of Russia, the dealing in iridium being prohibited in that country owing to the damage which particles of iridium gave rise to the dies used for gold coins, as the metal is so hard as to cause the minute grains to indent and deface the hard steel dies. Attempts have been made to obtain coatings of iridium by electroplating, but with no very considerable success, from the difficulty of finding any solution capable of dissolving the metal. At present iridium is used for the knife edges of chemical balances, for which purpose it is steadily supplanting agate. It is utilised for the hypodermic syringe of the surgeon, contact points of electric apparatus, and a variety of other purposes where durability is an object of importance. It may easily be seen how useful it could be made for photographic purposes. A burnisher faced with iridium would get rid of one of the great difficulties of that popular machine—the liability of the burnishing edge to become scratched from the action of small particles of grit acting during the burnishing operations, the steel having become softer through repeated heatings.

The British Association for the Advancement of Science has closed its offices in this country, its organising officers being *en route* for Canada. Most of the members and associates will also now be on their way, as the inauguration meeting takes place on the 27th inst. Our readers will join us in wishing all, particularly our photographic friends, a safe and pleasant voyage.

With the thermometer registering 92° in the shade, as had lately been recorded, the fortunate voyagers across the water will be envied by their scorched and baked compatriots who are doing their "level best" to take a good negative with the mercury at the top of the thermometer tube. Such tropical heat has not been experienced for sixteen or seventeen years, and it behoves all employers to look to every possible arrangement for the comfort of their printers and other assistants being carried out. Perhaps we should say arrangements for minimising the discomfort; for no one has had "comfort" for some time past.

Everyone may, at anyrate, congratulate himself upon the almost total disuse of collodion for portraiture. Temperature 92° Fahr. and ether vapour would have been too utterly insupportable.

The question of what to drink to assuage the tormenting thirst which is experienced by dark-room and printing-room hands is very important. The danger, quite apart from other grounds, to the photographer of using alcoholic liquids has been pointed out many times by us, and we strongly advise that they be not used. A well-known photographer of our acquaintance—one who works—tells us that nothing is more suitable than a mixture of soda water and milk.

On the 1st instant several new regulations in connection with the Patent Act of 1883 came into force. In the case of patents granted before the Act a patentee who had paid the prescribed fee of £50 before the end of four years from the date of his patent may, in lieu of the prescribed fee of £100 payable before the end of seven years from such date, pay the following annual fees:—Before the end of the seventh year from the date of the patent, £10; eighth year, £10; ninth year, £10; tenth year, £15; eleventh year, £15; twelfth year, £20; and thirteenth year, £20.

We lately alluded to M. Montigny's weather prophecies, and further details of his views are to be found in a little pamphlet just published at Brussels. Mr. W. Spring had determined that the colour of pure water in great bulk is blue, and on this fact M. Montigny grounds his system. The luminous rays, he argues, traversing the air, charged with large quantities of pure water, are necessarily tinged with the blue colour of this medium. The excess of blue in the scintillation of the stars thus becomes an almost certain means of predicting rain. This theoretic conclusion corresponds with the results of his observations, continued for several years past, in the appearance of the stellar rays in connection with the state of the weather. During the few months of fine weather in the present year blue has been much less conspicuous than in the corresponding months of the previous period since 1876, when wet weather prevailed. It also appears that green, which had always coincided with clear skies during the five years before 1876, has recently again become predominant. Hence, as we have said, he draws the inference that a cycle of wet weather has terminated, and that one characterised by a more normal condition of weather may be anticipated.

THE LATE JABEZ HUGHES.

Our readers will be concerned to hear that death has once more been at work in our ranks, the victim on this occasion being Mr. Jabez Hughes, who may be considered as one of the veritable fathers of photography. A protracted and painful illness, the crisis having apparently passed, caused the deceased to visit Harrogate for change and recuperation; but after a very brief stay he was ordered home by the doctors. Complications set in, and, after fighting the disease to the last, Mr. Hughes succumbed on Monday morning, the immediate cause of death being dropsy.

The last occasion on which Mr. Hughes appeared in public was at the funeral of his friend the late H. Baden Pritchard, that being the first time he had ventured from home for a period of three months. His condition and appearance were then the subject of general remark.

As we write we learn that the funeral is fixed for Thursday, 14th inst., at Abney Park Cemetery, so that when these lines are published the ceremony will have already taken place.

In our next number we shall give a portrait of the deceased gentleman, together with a full notice of his long connection with photography.

RETOUCHING FOR AMATEURS.

The production of portraits is a favourite pastime of amateur photographers at the present time, and is likely to remain so, in spite of the fact that the department of portraiture is the only photographic one in which amateurs have little or no chance of competing with professionals.

The work certainly has a charm of its own; and, even if the amateur can admit to himself—which he rarely will—that his portraits are not by any means happy reproductions of his friends, and attempt to put portraiture on one side altogether, his friends are not likely to permit him to do so. They will pester him to "take their likenesses," and he is persuaded to do so, although he knows well that little thanks are likely to be given him for the lugubrious productions which cost him so much trouble. He is handicapped in two ways: he has at least in ninety-nine cases out of a hundred no studio, and he has no knowledge of the art of retouching.

With regard to the first part of the difficulty: it may be said that there are certain styles of portraiture which can be produced quite as well, as regards roundness of lighting, in an ordinary room as in a studio, if due consideration be given to the use of reflectors, and so forth. With regard to the second it may be said that a *certain* skill in retouching is acquired without very much labour if only the amateur know how to set about it.

Of the elaborate modelling now so universally practised by professional portraitists I intend to say nothing, nor to enter into the question as to whether it is a commendable procedure or not. It is in the present day very much spoken and written against by those who do not practise it. Possibly there is something of the "sour grapes" in these mutterings, the decriers of the practice being, I believe, always unable to perform it themselves.

There is great difficulty for an amateur in getting any information on the method of going about such rudimentary retouching as he is likely ever to become an adept at. I believe that this difficulty arises from the fact that all those who have given instructions in retouching are themselves great adepts at the work, and that those who are very skilled in any manipulative art have great difficulty in communicating their methods to beginners, because they cannot bring their minds and hands back to the helpless state (with regard to the particular art) in which they were when they first commenced.

I remember once reading an article on the subject of retouching, doubtless by an able retoucher, in which he remarked that "a stipple could be produced in many ways; for example, by making little crosses or dots with tints." These may not be the exact words, but they convey his meaning, and, heavens! how senseless the *meaning* must have been to most amateurs—myself among the number.

For the reason indicated I have thought that it might be of use—at least to some—if there were given some account of the rudimentary retouching, which any amateur may easily acquire with a little practice, by one who certainly has not attained to any such excellence as to justify him in being unintelligible to beginners.

We will take a very common case. A portrait has been produced, and the artist, gazing upon it, comes to the conclusion that it would be a gem of art were it not for those few spots—possibly due to a defect in the plate, but more probably to some incipient freckles in the face of the original which are almost invisible to the eye, but which, on account of their yellowish colour, come out on the print with startling distinctness—were it not that one or two slight and almost imperceptible lines on the forehead have come out like the lines of care on the face of an old man, were it not that the diagonal lines passing from the corners of the eyes to the cheek appear much more marked than they do in nature, and were it not that there is a slight patchiness here and there. The probability is that the picture would not be a "gem" were all these defects removed, but it is quite possible that it would be a favourable portrait; and there is no reason why the amateur should not remove them.

All that is necessary in the way of apparatus is something to act as a retouching desk, a suitable lead pencil, and some "medium" to give the pencil a bite on the film. If the amateur have any skill in carpentry—even a very little—he may make a dish for himself; if not, he may buy one very cheaply. The object of the dish is as all know, to hold the negative in a good position, whilst it shades the light from the operator's head, the operator looking through the negative on to a sheet of white paper or a mirror according to the density of the first mentioned.

As for a pencil for the simple retouching to be performed, any good H or H H drawing-pencil will do well enough. The point must be kept *very* sharp. I have tried many "retouching mediums," but have found none of them to give a better tooth than is given by a drop of turpentine applied to the varnished film and worked till dry either with the finger or a piece of chamois leather over the part to be operated upon.

When all is ready it is best to begin upon the spots, as these are by far the easiest to eradicate. It is well to have a proof at hand to refer to. The pencil is applied gently to the spot and is lightly worked in a circular direction. The transparent portions will gradually disappear. Great care is necessary to press but lightly or the varnish is likely to be scratched and the whole labour of retouching will be lost—the only thing to be done when a scratch has been made being to dissolve off the varnish and to proceed anew. If the spot be a very dark one—dark on the print, transparent on the negative—a softer pencil may be used.

Perhaps the marks next to spots the most easy to eradicate or reduce in prominence are lines. The pencil is simply carefully worked along these. Even greater care is required in this case than in the case of dots to avoid scratching the varnish.

The lines which fall obliquely from the inner corners of the eyes, and also at times from the corners of the mouth, now require attention. They should be softened and shortened, but should not be eradicated altogether, or an unnatural result will be produced. To do this we begin at the outer extremity of each line where it blends itself imperceptibly with the rest of the face. Here we work very gently in a circular or spiral direction or in short strokes parallel with the direction of the line. We thus cause the lower end of it to entirely disappear, and working gradually upwards reduce the transparency of the whole of it, being careful to have an even gradation of density in such of the line as is allowed to remain. Somewhat the same process may be applied to the lines under the eyes, if these have come out darker than they ought to do. In this case the pencil is worked in short curves, the same as those of the lines.

Rather more difficult than the operations which I have described is that of a more or less general mottled appearance of the face. We are very liable to overdo our work in this case, and merely to substitute for portions too transparent others too opaque, giving a worse appearance than before we commenced. To avoid this we must work very lightly. It is well to begin at one "corner" of the face (if I may be allowed to use such a term) and gradually to work over the whole. Thus we may begin at the upper left-hand corner. We again work with the pencil in small circles or in short lines; and, whilst doing so, we must be particularly careful, as we proceed, now and then to look at the general effect which we are producing from a greater distance than that at which we are working. If we do not do this we will probably substitute patchiness on a large scale for the same on a small scale.

The amateur who has acquired by practice the power to eradicate the defects which I have mentioned will find that he is capable of improving his portraits to a very great extent. He may possibly aspire somewhat higher, and may wish to modify the too abrupt transition from high light to shadow which is so liable to appear in photographic portraits, especially those taken in an ordinary room. To do this is much more difficult than to perform all that has been already described.

It is necessary before commencing it to remove all patchiness. After this the pencil is worked very lightly in sweeping lines, following the direction of the boundary of light and shadow. The first few attempts at retouching are likely to be failures. This need not, however, in any way dishearten the beginner. The negative is not spoiled because it has been badly retouched. It is only necessary to apply a drop or two of turpentine to the part and to wipe it with a piece of chamois leather, when all trace of retouching will be removed and the process may be recommenced. W. K. Burton.

ON CHOOSING A SIZE FOR *CARTE* AND CABINET NEGATIVES.

In continuation of this subject, which I discussed a fortnight ago, I have now to describe the method I adopted for *carte* negatives and their storage. It may be remembered that I alluded to the change I made in my system of sizes selected and storage of negatives on account of the increased convenience in working *cartes* and cabinets on one size of plate, coupled with lessened cost of the new size and capabilities of diminishing the weight of the gradually-increasing stock of store negatives, which, as I kept them in an upper room, became a great responsibility in view of the stability of the architectural arrangements.

Taking, as I do, two *carte* pictures on one plate, it is evident that the only way of lessening weight was by making two negatives out of one plate, and only saving one of the two, which nowadays, when all negatives are retouched, is not a difficult matter, as it does not often happen that both sides of a double negative are equally good and equally worthy of being retouched. As a matter of fact my printing-stage was usually covered with much useless lumber in accommodating the non-selected halves of double negatives.

I had some difficulty in deciding how to cut the plate, as one single cut divided it into two pieces half-an-inch longer than the ordinary "quarter-plate," and the use of such a size would involve the making of special printing-frames. Yet, on the other hand, my old experience had taught me the inconvenience of the quarter-plate as a *carte* size; for, if the figure or head were not very well "centered" on to the plate, it was difficult to cut a *carte* out of the print without bringing in the edge of the negative. Again, too, if I decided to cut the glass down to the regulation quarter size two cuts with the diamond were involved; and, as this would be necessarily done by the printers, I had a very natural hesitation at taking such a risk—the more so when I felt that occasional need might arise, where the figures were ill-placed, to cut a small piece at both top and bottom to accommodate the figure. This, as it might require the removal of very fine pieces, involved the necessity for greater skill with the diamond than I felt I was justified in expecting. The question then simply became—"One diamond cut and negatives requiring special frames, or two to three diamond cuts and their risks, and power to buy extra frames at any time without having to wait for their making."

I chose the former and, I think, the better of the two. I had, of course, to wait after my order for frames was sent in to allow for its being executed, as it was utterly improbable that the size would be stocked anywhere; but there was very little inconvenience, and the delay, thanks to the energy of the maker, was only slight. I ordered such quantities as were likely to suffice for all possible requirements, even in a push of business. The size is more convenient in every way than quarter; and, whenever I come across the pile of disused printing-frames of the old seven and a-half size, I by no means regret the expense incurred by relegating them to the lumber department and filling their place with lighter and more convenient frames.

In storing them there was a very considerable gain. I had up to that time kept my negatives on grooved shelves, open back and front to the air, one seven and a-half negative reaching from back to front. Such shelving is expensive to put up, and, in addition, a considerable space is occupied by comparatively few negatives; but by using the long quarter-plate it became possible, by planting a narrow lath upon the grooving, to place two negatives in one pair of grooves, one series from one side and the other from the other side of the shelving. Those of my readers who adopt a similar plan will be well aware of its advantages, the same shelf space containing at least double the number that the old ones could hold of the seven and a-quarter size. This gain I still further increased by placing the negatives in lengthwise instead of upright, thus giving me a gain of an inch and a-half in every row—an amount that would allow room for two or three extra shelves in the lower negative-storing chambers.

For dividing my half-plates into two I simply employ a small board with a lath nailed on to the left end, a couple of pins being let into the board at top and bottom to serve as guide for the straight-edge. The negative is pressed against the lath, the rule is slipped against the pins, and the diamond cut is given with certainty.

Finally: I may say that I do not make any claim for novelty in the system I describe. I have merely given it with a hope that it may contain hints for anyone who is about to establish a studio, or may be contemplating a change in the size of his *carte* and cabinet negatives. G. Watmough Webster.

ON PHOTOGRAPHIC BACKGROUNDS.

It does not appear that photographers pay so much attention to the production of backgrounds as formerly, but trust more to the stock subjects of the dealers to supply their needs. Compared with the monstrosities of former times there is much improvement; yet many of the higher class backgrounds of the present are not in keeping with the majority of sitters, and are not always remarkable for pictorial qualities.

The idea has often struck me that photographers do not make use of the scenes which surround them as they might, the principal reason being, I suppose, that the cost of a specially-painted background is at present so much more than that of one from a stock pattern; yet this scarcely need be so. New subjects could be outlined in, and even painted fully, for the purpose of photographic scenery from a picture projected upon the canvas by means of the lantern, and thus introduce a great deal of the mechanical and, therefore, less costly element into their production, by economising the time of the artist, who should still be a first-rate one at finishing.

It is probable that there is a good opening for the manufacture of backgrounds from photographers' own subjects if a good article could be supplied at only a slight advance on that of the stock one. The interest would be much greater if a portrait were taken with a local scene instead of being backed-up by something foreign in itself as well as to the sitter. The plea could scarcely be urged for any neighbourhood that there was nothing suitable for the purpose. It would, indeed, be a poor one which had no "beauty spot." In this place (Littlehampton) there are several; but one, in particular, which exhibits all the characteristics of the place in so highly-interesting and pictorial a fashion that one can almost imagine Nature to have specially designed it for the purpose of portraiture. Lest there should be any difficulty respecting the point at which to place the sitter, there is a stump for mooring ships to mark it. As the top of this is usually covered by someone its suitability is apparent. I have noted similar views in other places in which there has been nothing "loud" to detract from them as accessories if painted in detail. Picturesque street views, forest scenery, portions of old ruins of abbeys and castles, might be represented.

The chief consideration in making the photograph, and to avoid incongruities of perspective, will be to make up one's mind at about what point in it the sitter's bust will appear to most advantage, making that the point of sight for the camera, and that the object in that direction may be formed on the focussing-screen in the axis of the lens. Let it be borne in mind that a slip off the side of a picture will not answer. The bust of the sitter being the point of sight, the vanishing point of the background picture must be in the same direction, immediately behind. Sufficient attention is not paid to this requirement; hence the frequency of pictures in which the sitter in respect of the background has an impossible look.

Those photographers who have slack periods, and possess a certain amount of freedom of hand (when the paint brush is in it), may with the help of a sciopticon paint their own. The introduction of this piece of apparatus reduces the operation almost to a mechanical one, and may on that account disgust some of our artistic readers. Be that as it may, no doubt the majority are like myself, who prefer to take the shortest and easiest path, not being over-anxious to see how much trouble he can put himself to, provided the result is not inferior.

The materials required for oil-work are a size of suitable canvas, a wooden strainer, a pound and one or two other paint tools, and three or four pots containing as many different grades of the background tint of spirit "flatting."

After straining the canvas upon the frame, or nailing it up to a wall, the laying-on of the ground colour, consisting of that grade which will prevail as middle tint, is proceeded with, and allowed to dry. The operation may be then repeated to get body or to correct colour, making it lighter or darker, if necessary. As this ground constitutes the greater part of the finished article some trouble should be taken to get it quite right. When thoroughly dry it is ready for the picture. Of this have a thin positive and negative, similar in size, to be inserted and registered in the same position in the lantern. The former being clear in the lights will enable the painter to put them in more easily, and the latter having the same quality of transparency for the shadows will give the same advantages in respect of those. Place the negative in the lantern first, and project its image of the desired size upon the prepared canvas; then proceed to sketch in the picture, and fill in the half-shadows with the next lower grade of colour, taking care, of course, not to obstruct the light from the lantern by your presence more than you can possibly help. Do not overdo this first painting in depth; it is an easy matter to strengthen any parts that require such treatment when the lights have been added. Now remove the negative from the lantern and insert the positive in its place, so that its enlarged image may be exactly superimposed upon that of the negative's, and paint in the half-lights, after which let daylight in upon the work, and "take stock" of it.

If the operation have been fairly well performed the canvas will present a flat-looking scene, rather too dull for the office it is required to fill. The heightening of the lights and deepening of shadows may now be done with the remaining lighter and deeper grades of tint, and any rottenness or unevenness in any part of the picture made firm and smooth. For cloud and atmospheric effects a softener will be a useful addition to the tools employed. The painting of a photographic background will not be found a very difficult operation if the most trying part—correctness of drawing—be ensured by using the enlarging lantern.

Very much the same procedure may be followed if the work be done in distemper. The colours employed should be rubbed up in thin boiled starch and applied in the liquid state, or made up into crayons and used wet. The former will, however, be found most convenient. Lay on the ground colour with a whitewash brush, rub it well into the canvas, and apply a coating to the back, if necessary, to secure a good, solid base. When dry, work over it with a stiff hair brush or a roll of coarse rough paper to reduce inequalities of surface and produce uniform deadness. It is then in a condition to receive the picture.

It will be found more tedious to sketch in with water-colour or distemper, because it does not flow so nicely on account of the rapid absorption of water by the ground. There must, therefore, be greater freedom with the brush or messiness will soon be apparent. Distemper, however, is the thing for plain backgrounds, effects of cloudiness and gradation of tint being readily attained by its means. As it has been repeatedly described in these pages I shall only briefly allude to it.

The square of canvas is strained upon a frame and wetted. Various grades of grey are then rubbed into it, according to their strength—usually the lightest of the series at the top and the darkest at the bottom. While the canvas is still wet a moderately stiff and open-haired brush is worked in a circular direction over it, likewise commencing at the top and working downwards; or, if the top be too light, it is worked upwards, always taking care to work gradually out of the one into the other to avoid cloudiness of the wrong kind. When dry it may again be worked over with a roll of rough paper, which still further equalises, but has a tendency to lighten, it in tone. After these operations, if it be still not to one's liking, it should be wetted up from the back and powdered crayon of suitable tint sifted over those parts requiring modification, and worked again with the brush to prevent spottiness. Its depth of tone can be altered, or it may be freshened up at any time by repeating the wetting. JOHN HARMER.

LENSES WORKING AT CROSS PURPOSES.

It was a singular comment upon the boasted fine definition given by a photographic objective which is not now constructed—the orthoscopic lens—that a mechanically-fine example of one of these, of presumably the largest dimensions yet constructed (the front lens being four inches in diameter and the maker being an optician who was, if anything, rather unusually fastidious), and which was submitted for examination last week at a meeting of one of the societies, should have been certified by at least two experts by whom it was carefully tested to be seriously defective as regards that very quality for which it has long been famed, namely, sharpness of image.

The maker, who was a scientific as well as a manufacturing optician, had made a perfect study of the conditions under which sharpness was obtainable by means of this combination, and in consequence of such study had written the only treatise extant in the English language on the advantages of this combination. Petzval, too, the inventor of the lens, had obtained by its agency such a high degree of definition as to have led him to employ it as the object-glass of a telescope, the image formed by its means being capable of examination through a powerful eyepiece. Notwithstanding all this, this large specimen of the lens in question was unmistakably defective in the very quality for which it had been previously renowned. How could this be?

The first surmise in a case of this nature is that expressed in the question—"Were not the lenses changed?" To this we reply that such skilled, sharp-sighted observation as could at the present time (the creative factors in the question have all "gone on!") be brought to bear upon a critical examination, point to this verdict—that the particular lens in each cell is the work of the professed maker, and that the burnishing-in of the lenses in their cells was effected under such circumstances as to leave no room to doubt their genuineness.

On second thoughts we see no good that can result from making any mystery of the paternity of the lens to which we here draw attention. It is an orthographic combination of the largest dimensions and highest pretentions, made by Andrew Ross at the time when he was specially assisted in this department of his business by his son, Thomas Ross, and his son-in-law, J. H. Dallmeyer—all since deceased. To think that these *haute noblesse* of optical science in their day would permit one of their productions, in which so much pride was felt, to go to the public in an imperfect form is preposterous. How, then, is this lapse to be explained? We believe it is capable of being explained upon very simple principles, and to do so is the object of this article, because it recognises a principle susceptible of application to more lenses either than this one or any emanating from a particular factory.

We have said the lenses in this individual case were stated to be genuine. Having seen the objective in question our own opinion coincides with this verdict. But we do not forget that on one occasion a large portrait lens, by an eminent maker, was submitted for examination, the character given of it being one that was essentially bad, notwithstanding the fact of its being procured direct from the maker. Crucial investigation disclosed the fact that the front lens of the objective complained of did not belong to *that series* at all but to another; but, as both were of the same diameter and set in cells, the screws of which were similar, the individual to whom had been entrusted the final wiping of the surfaces with wash-leather and the packing of the lenses in soft tissue paper had inadvertently screwed the front lens of one into the mount of the other, resulting in both objectives being found to turn out badly.

To apply this to the case before us: this, too, was the opinion we entertained, and when, by making an offhand experimental trial of other fronts of shorter focus applied to the same back, and finding that by means of one of a focus several inches shorter we obtained magnificent definition, even with full aperture, we then knew that a change of some such nature as that hinted at had been effected. A four-inch portrait lens had probably been allowed to go forth to the world with a front far more powerful than there was any occasion for; while, on the other hand, as in the present case, a front possessed of too long a focus to harmonise with the back left in the mount was the result of the *mésalliance*.

When an orthoscope or orthographic objective gives imperfect definition, the probability is that this can be remedied by increasing the power of the front element. In general terms the more powerful the anterior lens the more intense will be the definition and illumination; but we do not allege this to be always the case. There is a suitable balance that must exist between the anterior and posterior combinations in a lens whether it be an orthoscopic or a portrait objective. The back lens corrects the aberrations (spherically speaking) of the front for axial rays, and also lengthens oblique pencils so as to bring them to a focus on a plane which is as near as possible to that upon which the axial focus falls.

In conclusion: if a lens bearing the name of a maker of eminence is found to be bad, it is a safe inference to conclude that some change has been made in its constituents since the moment the maker had it upon the "horse" for the purpose of being tested. Into the precise nature of such change we do not here enter.

ON ORGANIC DYES AND SOME PHOTOGRAPHIC USES OF CARMINE.

The relative merits and demerits of different classes of colouring materials, and of the solid substances by which they are held in suspension in films, will have to be experimentally ascertained before the best light for the development of photographic plates is obtained; for, although much has been done of late in improving the light of the developing-room, there is a certain amount of empiricism in the methods, with considerable room for better results than any yet seen. On the present occasion I intend to say nothing about translucent window or lantern screens, in which, after myriads of reflections and refractions in the interior of the substances, the light finally gets through, greatly weakened by the passage, before it reaches the eye. A certain amount of safety in the developing-room can be obtained by colourless translucent screens alone, a certain amount of safety can also be obtained from coloured transparent screens, and a certain amount of safety likewise from translucency and colour combined. In experimentally ascertaining the numerical values of these influences, it is best to keep them separate; that is to say, to obtain translucency by means of colourless translucent films, and to obtain colour by means of transparent films, so that the two methods shall not be used in a single film, thereby placing difficulties in the way of ascertaining their relative values in the production of a safe yet strong light for developing.

The long prevalent idea that the best light for developing is exclusively one as close to the extreme red of the spectrum as possible has of late been proved to be practically erroneous; one of the chief of the three or four reasons for this is—the comparatively weak impression made by those rays upon the nerves of sight, so that if the yellow from the same source of light be taken instead of the red, but reduced to half its normal intensity by translucent screens or otherwise, the half-power yellow may yet have more physiological influence on the retina than the full-power red, and be as safe or safer to work by because of its comparative reduction in intensity. This does not prove that previous hypotheses about developing-room illumination were wrong, so far as they went; but that they were erroneous for practical purposes because other conditions were not taken into account. Yellow, as proved by photometric experiments, has far more luminous intensity than any other portion of the spectrum, but this may be due solely to the construction of the eye, and bear no relation to its comparative influence upon photographic films.

In the production of transparent screens we have the choice of mineral, vegetable, and animal colours. As a general rule, the mineral colours are the least brilliant but the most permanent; the vegetable and coal tar colours are more brilliant but more fugitive, especially under the action of light; the animal dyes are usually more permanent than those of vegetable origin, and equally brilliant. Coal tar dyes are more permanent upon an animal than a vegetable fabric; that is to say, more permanent on wool and silk than upon cotton and linen. For the same reason it is best in all cases, where possible, to apply these dyes dissolved in albumen or gelatine rather than in varnish when coating glass or fabrics with them for photographic purposes. In the dyeing trade there is a great demand for albumen, despite its high price, because it conduces to the permanency of certain aniline colours.

Mr. Leon Warnerke found that his window screen, dyed with aurine, was bleached by light to a large extent during his prolonged absence in Russia. He does not say whether he selected wool rather than cotton to carry the dye, and whether he cleaned, bleached, and mordanted it as dyers do before applying the colouring matter, that the latter might be fixed in the very fibre of the material. Had he done so the life of the screen would have been prolonged; but exposing a screen of this kind constantly to "the garish, glaring eye of day" is straining it beyond its powers. This, from my point of view, is no argument against the value of the screen; for I feel convinced, from experiment and theory, that no man can possibly have the best obtainable light in his developing-room when the original source is constantly varying daylight, exceedingly rich in actinic rays. In the best light of the future unsteady daylight as the primary source will have to be abolished altogether. A screen which is safe with light of one intensity is not necessarily safe with a light of higher intensity; but, if it be, the operator, in the first of the two cases, obviously works with a worse light than the necessities of the case demand.

Films of organic colours, for lanterns, may be expected to have a long life, and can certainly be easily and cheaply renewed. They should not be liable to injury from the heat of the flame; for the lantern should be a large one, with its flame some little distance away from the coloured screen, so that it does not strain the optical powers of the latter to the utmost. Taking all the points into consideration it seems probable that the extra brilliancy and transparency of organic dyes may be utilised with advantage as compared with the less bright but more permanent colours of stained glass.

Of the animal organic dyes there are but two of leading importance in commerce, namely, carmine and lac, both obtained from insects. The exquisite colour, carmine, has been sinking in price of late years, because of the advent of the aniline dyes. My sample, of the very best quality, was obtained at two shillings an ounce from Messrs. Becker and Co., Maiden-lane, Covent Garden, London; a few years ago the price would have been seven or eight shillings an ounce. There are several qualities of carmine, many legitimate as well as illegitimate ways of preparing it, and two varieties of the cochineal insect from which it may be derived. Pure carmine is totally soluble in water of ammonia, which usually leaves foreign matters and adulterations behind.

A suitable solution for coating glass plates is made by dissolving carmine in albumen to which one fourth its volume of strong liquid ammonia has been added. The albumen should first be whisked into a froth, and allowed to stand all night to subside. When the solution is weak in carmine the films on glass have a pinkish-red colour, and absorb chiefly portions of the green rays of the spectrum. With stronger solutions all the green and nearly all the blue rays are absorbed, and with stronger still all the more refrangible rays than the yellow are cut off, the yellow being next attacked. At this stage it much resembles ruby glass in its action on the spectrum, there being a tendency in a strong light to let a feeble trace of blue through; but the carmine film has the advantage over ruby glass that it has a brighter colour, and transmits more useful light, area for area. Altogether it makes a better screen when the original source of light is not of great intensity; and artificial lights of low intensity should, in my opinion, always be the primary source of developing-room illumination.

Just as two sheets of ruby glass give safety from all trace of blue by general absorption, and lowering the useful light in the room, so is the same effect produced by superimposing two intense carmine films. The preferable plan is to use one of intense carmine to get rid of the green and almost all the blue, then to cut off the trace of blue and violet by a second sheet of glass coated with one of those yellow dyes which absorb the more refrangible rays powerfully, but permit the red and yellow to pass freely. The optical properties of some of these yellow dyes I will deal with on another occasion, for I have made a long series of experiments on their characteristics likewise.

One of my objects has been to prepare glass lantern screens, each consisting of one or more dry films, to give the chief true colours of the spectrum. Already I have obtained a pure green when the light is moderate; when the light is very strong a scarcely visible trace of the extreme red of the spectrum comes in. The red glass in the market flashed with copper oxide on one side and silver on the other gives a nearly pure red; with a strong light it passes a trace of orange.

There is, however, difficulty in obtaining a pure yellow. Lord Rayleigh, the coming President of the British Association at Montreal, has tried to obtain a pure yellow by means of troughs of coloured liquids, but says that he has not been altogether successful. He adds:—"The best was a mixture of bichromate and permanganate of potash with a salt of copper (sulphate or chloride). The first removes the blue and violet, the second the green, the third the red, and thus the yellow is isolated in considerable purity. This liquid is very unstable. The comparison of the simple and compound yellow (which nearly matched) was interesting. One was transparent to the sodium flame, the other completely opaque to it. When the two are brought together so that the light has to traverse both, almost complete darkness results, even when the brightest clouds are used. I should mention that it is only when the light is strong that any of these liquids give yellow in full perfection; otherwise the colour is more nearly described as brown, which is, in fact, identical with a dark yellow or orange. The best natural yellows, such as chrome, are partly simple and partly compound, returning all the light which falls upon them except blue and violet. It is clear that neither a purely simple nor a purely compound yellow can rival them in brilliancy." The difficulty in obtaining a pure yellow the carmine films are likely to help to overcome, by making them of such intensity as to cut off the green without interfering with the yellow, whilst chloride of copper of suitable strength may be used to cut off the red rays. When it is too strong it cuts off the yellow also.

By means of a pair of carmine films, with a little suitable yellow added, a purer red has been obtained by me than is given with the "stained red" glass, as it is called; for the latter passes a trace of orange when the light is strong. Carmine, without yellow intermixed, is very unsafe for developing-room illumination, unless the film or films be of sufficient depth of colour. Then it is safe.

The attention of Dr. Vogel and others who are trying to increase the sensitiveness of dry plates to the less refrangible rays of the spectrum might be given to carmine, with its strong power of absorption of some of the true green rays. It does not readily absorb one portion of the green.

Carmine dissolves freely in albumen and ammonia until a fairly intense film is given on glass by the solution, but on increasing its strength beyond a certain point floating red specks form in the liquid; such, at least, is the case with my sample of the dye. Hence it might be well to first levigate the carmine with the alkaline albumen, and afterward dilute down the mixture with more albumen and ammonia. The solution of several of the aniline dyes in the same liquid can similarly be greatly hastened by trituration and levigation, whilst others dissolve freely without any necessity for such mechanical operations. The porphyry slab and muller of the druggist is a useful instrument for such levigation; but an Italian artist—a friend of mine—makes a thick and even magma of any desired colour, simply by means of two flat slabs of glass, one larger than the other—the smaller one being used as the muller, the larger one as the slab. In a common pestle and mortar the points of contact are not large enough for purposes of levigation; the Germans, however, have a useful flat-bottomed mortar and flattened pestle to do this kind of work. The albumen acquires a slightly more gelatinous consistency after the addition of the carmine; in fact, a solution of carmine in plain water and ammonia is itself slightly gelatinous. The red specks previously mentioned sink when the liquid is allowed a day or two to rest, so it is advantageous to keep the solution in a long, narrow bottle; in fact, in all experiments with dyes in albumen or other menstrua it is well to use tall, narrow bottles, on broad, flat stems.

Carmine is made from the cochineal insect, a Mexican shield-louse, of which there are two kinds—the one covered with a cottony down, the other bare. The latter is the more valuable insect of the two. The unfortunate creatures are killed by drying upon hot plates, by immersion in boiling water, or by baking in ovens, which processes deserve the attention of the Society for the Prevention of Cruelty to Animals. The dried insects keep for very many years if not exposed to damp. The most simple way of making carmine is to pour a solution of alum into a decoction of cochineal; but there are many processes, some of them peculiar to particular continental towns, and in all of them boiling forms an important part of the operations, the duration of the application of heat being of moment. Like the aniline dyes, carmine is sometimes adulterated with starchy matters. Occasionally vermilion is added, which increases the weight and reduces the brilliancy of the colour.

W. H. Harrison.

ROYAL CORNWALL POLYTECHNIC SOCIETY.

The following is the list of awards in the Photographic Department of the Annual Exhibition of the Royal Cornwall Polytechnic Society, which opened on Tuesday last. A more detailed account of the Exhibition will appear in our next:—

Professional Photography.

First Silver Medal	W. W. Winter.
First Silver Medal	W. Gillard.
First Silver Medal	H. P. Robinson.
Second Silver Medal	Geo. Hadley.
Second Silver Medal	L. Berry.
Second Silver Medal	T. J. Dixon.
First Bronze Medal	W. P. Marsh.
Highly Commended	J. Milman Brown.
Highly Commended	R. Faulkner.

Amateur Section.

First Silver Medal	A. Pringle.
Second Silver Medal	A. G. Tagliaferro.
First Bronze Medal	W. J. A. Grant.
Second Bronze Medal	P. H. Emmerson.
Highly Commended	P. H. Emmerson.

Photographic Appliances, &c.

Second Bronze Medal	F. B. Dagley.
Second Bronze Medal	R. R. Beard.

WHERE TO GO WITH THE CAMERA.

[It is hoped that this series of articles will be continued at regular and frequent intervals during the vacation months, and we shall be glad to receive contributions to the series from any friends able to treat of new and interesting ground.]

BEESTON CASTLE, BUNBURY, AND PECKFORTON.

On a bright, clear, and promising morning in the early part of May, 1884, at 8.20, ten (more or less) enthusiastic members of the Liverpool Amateur Photographic Association left the Birkenhead Station for Beeston Castle, &c. We quickly reached Chester without any noticeable incident, except that we had the pleasant and consoling assurance from our own special "weather prophet" that on account of a vague clearness over the Welsh hills we should not get off "Scott"-free from rain, although to present appearances the only "wet" we were likely to see would be required to supply the vacuum which the heat of the day would cause. Here we gazed anxiously around for signs of a missing member of the party. At last we were startled by discovering a gorstly and shapely sarcophagus of solid leather, something under a ton in weight, with a pair of legs reposing placidly behind. This, we at last concluded, must know something about our missing friend; but, as the solid bulk could not give any connected account of itself, we, after sorrowfully contemplating it for about fifteen minutes, wondering if the owner were inside, sadly and dejectedly went our way to the train. But to our joy the absent one turned up from a morning walk round Chester, just in time to get the object of our solicitude stowed away in the van for safety. A little further on we were joined by our worthy President (and his new $7\frac{1}{2} \times 5$).

On reaching Beeston we found that, it being Beeston Fair, no conveyance of any kind was obtainable, except a wheelbarrow, which we respectfully declined. Then came the question—How was the case to be conveyed? It might have been carried *à la* sample of grapes from Canaan slung from a tripod between two strong men's shoulders, but no "two strong men" volunteered. At last a porter was obtained—no other than one who was understood in his time to have been the smallest man in the world, but having commenced to grow, found, like Othello, his "occupation gone." A move is made at last, after sundry quenchers of milk, soda, &c, &c., through the fields, bathed in a flood of glorious May sunshine, with scarcely a ripple among the leaves—a perfection of photographic weather!

Beeston Castle, built about A.D. 1250, by Blundeville, sixth Earl of Chester, must have been an almost impregnable fortress, and was never reduced by open assault. The surrounding walls are nearly a mile in extent, and the apex of the hill is crowned with a citadel, defended by a deep and wide ditch, and entered by a very picturesque, steep, and narrow pointed doorway. In the interior is the great well, nearly 400 feet deep, round which many county traditions linger.

Curving round the base of the massive rock or hill surmounted by the castle, we reach the great gates. Here is found a picture comprising the old doorway and cottages beyond, with the Peckforton Castle in the distance. Cameras are all unloosed, but on the ground glass the view is not so satisfactory as to the naked eye; consequently we pass through the gate, and wind up the sinuous "covered way" to the top of the hill. Here a glorious panorama unfolds itself to our delighted vision. Far and wide the eye roams over the level plain of Cheshire (well named the "Vale Royal of England") shimmering in the summer sunshine:—Eastward, the horizon line is filled with the hills of Stafford and Derbyshire; northward the vision wanders from Northwich and Stockport round to Alderley Edge and down to Sandbach and Crewe; westward, the tower of Chester Cathedral leads the eye to the Welsh hills in the calm, far distance. All the intervening landscape at our feet is filled with pleasant farmsteads and shining waters, strung together like pearls by the thin white lines marking the highways.

But we must withdraw from the contemplation of the distant scenery to the work more closely at hand, and what a battery of cameras, old and new, are pointed at the old castle! Here a scenograph lowly stoops its modest head; there a more ambitious 10×8, or whole-plate, or 7×5, are dotted about; but whole-plate votaries are in the majority, and, indeed, we are glad to find that that seems to have become again the favourite size, being capable of making pleasing pictures without being too cumbersome for a comfortable day's tour. Soon each "Cyclopian" machine was at work on the castle gateway and marvellous ditch cut out of solid rock, terminating in a picturesque and impassable gorge. Tempting long-focus "shots" were essayed at the Peckforton Castle on the opposite ridge of hills, bearing some resemblance to the Cat and Mouse castles on the Rhine. After about an hour and a-half's work in blazing sunshine it was thought we had earned lunch, and sandwich boxes were rapidly emptied under the grateful shade of the trees, while efforts were made to secure the prize picture—*Repose*.

Leaving the castle hill, we take a pleasant footpath winding through a shrubbery and across two or three fields bringing us into a picturesque lane, well shaded with overhanging trees and closely skirting Peckforton hills. Hard by stands a pretty black and white grange. To the left we pass through a rustic gate into the Peckforton woods in search of Pennsylvania, temptingly described by Murray as "an artistic gem."

The cart-track leads us up, up, and the evident beauties of the present scene are neglected for the prospect of what is to come, showing the folly of not taking heed to the Æsopian fable of the dog and the shadow. A turn of the road, and Pennsylvania is before us; but where, oh! where! is the artistic cottage? In its place we found a restored slated building that was perfectly contemptible from a photographic point of view. Blessings and grateful thanks were *not* showered down on the head of the conductor, and "Pennsylvania" became the standing joke for the remainder of the day. Nathless, the sylvan glades and silver birches were worth, and obtained, a plate or two.

Passing down through the woods, artistic corners, gnarled tree trunks clothed with dainty foliage, and quaint road-turns, reveal pictorial compositions requiring only an appreciative eye to see them. Back to the old lane again and to work on the quaint black and white thatched cottages, and to long shots at Beeston Castle. Here we press into our service an antique dame who looks almost coeval with the surroundings. But now the light, which had been so favourable, had for the last hour or two been going from bad to worse, and as we finished work in this romantic lane we saw the last of old Sol for the day, and the gathering haze prohibited our intended distant view of Peckforton Castle. By devious courses we strolled back to the hotel for a satisfactory wind-up and substantial tea. Deferring our intended visit to Bunbury Church, with its graceful columns, recumbent marble figures, altar tombs of the middle ages, and old family chapels, for another excursion, which shall also embrace the old and characteristic Cheshire mansions of Ridley and Spurstow, the antique parochial chapel of Woodhey, and perhaps Cholmondeley Hall.

Mine host at the Beeston Castle Hotel had fortunately done justice to himself and to this illustrious Society, and the final arrangements were voted "last but not least." In conclusion: in deference to the wishes of a correspondent who thinks that it would be useful to state the *focus* of the most useful lenses for particular landscape excursions—I may say that, "on this occasion," lenses were used varying from three inches to eighteen inches focus, and almost every length between!!

A. W. Beer.

FOREIGN NOTES AND NEWS.

Professor Vogel on the Development of Landscape Dry Plates.

In the *Photographischen Notizen* Dr. Vogel says that, having remarked that in America the pyro. developer, which had been rather neglected for a time in favour of the newer oxalate developer, was again resuming its place as first favourite, he has frequently been asked whether that meant that he himself also now preferred the pyro. developer. Pyro. having the undoubted advantage of working quicker than the ferrous oxalate, he does certainly use it oftener than he formerly did, and he admits that with sufficient experience the same gradations of tones may be obtained with the pyro. as with the ferrous oxalate developer; but then the former is apt to carry green fog in its train, though, on the other hand, it is easy to remove the fog again by laying the fogged plate in a solution of iodine one gramme, iodide of potassium four grammes, and water 1,000 c.c., until the green fog becomes yellow, then placing it in hypo. until the iodide of silver formed be removed, and, finally, washing carefully. The green fog is also said to occur with the ferrous developer, but Dr. Vogel has never observed it. On returning from his American journey he brought a number of plates with him, which he developed in the following way, keeping in view the circumstance that he never knew whether the plates to be developed were under- or over-exposed:—A plate was first laid in 150 c.c. of a neutral 1 : 3 solution of potassic oxalate and 5 c.c. of a 1 : 3 iron solution, and a watch kept for the first appearance of the image. If in the first minute and a-half only the highest lights appeared, the plate was considered to be properly exposed. It was then removed into a second bath containing 150 parts of potassic oxalate to ten of iron. Meantime a second plate was laid in bath No. 1. If plate No. 1 did not seem to progress in bath No. 2 it was removed to bath No. 3, containing twenty parts of iron to 150 parts of potassic oxalate, in which the development was generally completed. The under-exposed plate, however, gave nothing in from two to three minutes in bath No. 1. It was then dipped into bath No. 2, and, subsequently, into No. 3, and, lastly, into No. 4, which contained fifty parts of iron to 150 parts of potassic oxalate, and here it was developed to the end. If the plates appeared very quickly (within half-a-minute) in bath No. 1 they were placed in a special bath of the same strength, to which five to ten drops of a 1 : 10 solution of bromide of potassium was added in order to prevent the development from going on so fast, and to allow them to become sufficiently intense. Afterwards they were, in order to finish the development, passed into baths richer in iron and corresponding to baths No. 2 and No. 3, but always with the addition of bromide of potassium. When three or four plates had been developed in the baths they were strengthened by having five, or in the case of the stronger ones, ten, c.c. of iron added to them, and a new bath made up instead of No. 4. In this way all the plates developed very slowly, it being quite half-an-hour before they had passed through all the necessary baths; but, in consequence, they all became sufficiently dense to do without intensification, save in exceptional cases. The time required for each separate plate also allowed of four plates all being developed at once, each at a different stage. Of course one had to pay attention that a plate did not go too far. That did occasionally happen, but not often. On one occasion he had some plates that had been taken on the table lands of Arizona and New Mexico, to which he had given an average exposure of seven seconds with the smallest stop—an exposure which had proved quite right for the North Pacific Railway; but all the pictures taken at this great altitude proved over-exposed. Bunsen has already shown that in high-lying districts the chemical power of light is greater than in low-lying ones, but Professor Vogel had not expected to find the difference so great as it was. Over-developed plates he reduced with iodine. He has never been pleased with cyanide of potassium since some films slipped off under its action, which has never happened with iodine, the latter being more under control. The solution employed was that mentioned above as being used for the removal of green fog, or if more rapid work were required the water might be reduced by one-half. The plate is left in the solution a few minutes. Part of the silver of the image will be converted into yellow iodide of silver, which makes the plate lighter. It is then dipped into hyposulphite of silver to remove the iodide of silver. Should the plate not yet be sufficiently reduced repeat the treatment with iodine. If the reduced plates have become too thin intensify with chloride of mercury and ammonia. Professor Vogel goes on to say that anyone who has only taken portraits in a studio with dry plates will be inclined to laugh at all these details, but not the landscape photographer, who, after returning from his journey, has no means of replacing an unsuccessful plate. A distinguished amateur was quite astonished to learn that Professor Vogel frequently spent more than an hour trying to "doctor" up a single plate.

PHOTOGRAPHERS' ASSOCIATION OF AMERICA.

FIFTH ANNUAL CONVENTION.

The fifth meeting of this representative body was this year held in Cincinnati, Ohio. It will be remembered that the meeting of 1883 was held in Milwaukee, Wis., those for the years preceding being respectively, dating backwards, in Indianapolis, Ind.; New York City, N.Y.; and Chicago, Ill.

The reports of the Convention yet before us are extremely meagre, the Cincinnati newspapers being either unable or unwilling to devote much space to the proceedings. It certainly cannot be that they do not consider the proceedings at the annual Convention of the Photographers' Association worthy of being reported, and yet, from such newspapers as we have seen, such a deduction would be justifiable.

The first day's proceedings are described as follows (and we distinctly wish it to be understood that our authority is that specimen of the Cincinnati daily press which, so far as we can learn, has devoted most space to recording the transactions):—

The Convention was called to order about ten o'clock [on the forenoon of Tuesday, the 29th ult.] in the spacious dining apartments of the Music Hall, with W. H. Kent, of Rochester, N.Y., President, in the chair, and Leo Weingartner, of Cincinnati, Secretary, having charge of the minute books. To the eye of the reporter it seemed that over one thousand delegates were in seats at this morning's session, who listened and took part in its proceedings.

The regular routine business, such as organising, report of the Committee on Credentials, &c., was proceeded with. The President's annual address was next in order.

During the course of reading hammering was heard, and the chair was interrupted. After a little reflection he announced the important fact that he did not prepare an address to be hammered out. (Laughter.) [We are unable as yet to publish this paper, which, we have no doubt, will be found worthy of Mr. Kent. Our local authority merely says:]—The paper dwelt on the success of the organisation and the interest derived from a brotherhood.

The Secretary announced the programme of entertainment. He said that the guests would have the privilege of witnessing that evening a fine display of fireworks at the Highland House, prepared for them by Colonel Harff, and that tickets could be obtained for thirty-five cents. Tomorrow afternoon the delegates were invited to start from the Music Hall in a body to the Cincinnati Northern depôt and then make for the Zoo. Those wishing to go along will have their thirty-five cents ready. The evening will be spent in dancing.

It is well to view a subject from more than one side; hence we find in another Cincinnati daily newspaper (the *Enquirer*) that on the opening day the technical proceedings, which commenced at ten o'clock, terminated at noon, during which time two short reports were followed by a pithy speech by the President, after which an adjournment took place. Speaking of the exhibition this paper says that there were hundreds upon hundreds of specimens of photographic portraits exhibited, from life-size down to vignettes.

The second day's proceedings are summed up (we still quote the same authority) in the curt statement that, after a paper on photography had been read, "a resolution was adopted to raise the prices of photographs." But the authority, to which our first reference is made, condescends to give us somewhat more, albeit still very slight, information relative to this second day's work. It says:—

A business session was held at ten o'clock in the morning, President Kent, of course, presiding, and Mr. Weingartner acting as Secretary. After the reading of the minutes and other routine had been gone through with, Mr. J. F. Ryder, of Cleveland, was introduced as the orator of the day. Mr. Ryder then read a most interesting and valuable paper upon the subject of the *Management of the Photographic Business.* The gentleman concluded his remarks by recommending a raise of prices among photographers, claiming that the artist who will turn out cabinet pictures for \$2 or \$2 50 must necessarily "make a bad job of it," while good workmen are made to suffer by his cutting of prices. In the future \$3, \$5, and \$8 will probably be charged for cabinet photographs.

Mr. James Inglis, of Rochester, moved that Mr. Ryder's address be published in pamphlet for gratuitous distribution to the profession; but it was finally determined to wait and print the entire proceedings of the convention.

This authority becomes quite enthusiastic when describing the post-business transactions. We append an account of the proceedings connected with the photographing of the group of the members according to time-honoured custom:—

"The real idealised was given a splendid illustration at the Music Hall yesterday. Just before the convention of photographers started for their little excursion to the Zoo, the delegates were all assembled upon the steps of the great Springer edifice in order to have a picture taken of them in a group. A huge camera was got ready upon the opposite side of the street, at the Washington Park gate, which was to be operated by Mr. Ingalls, of Rochester, N.Y., while Mr. Seavey, the famous background painter, arranged the "sitters." Then the fun began. All the street Arabs, pan-fish, hoodlums, and stragglers from the park began to push to the fore. All, of course, had something to say, while amid the babble of voices the shrill whistle of the small boy could be heard, and cat-calls and peals of laughter so augmented the frightful din that chaos seemed to have come again. Then other photographers broke from the crowd, and seizing cameras, lenses, and plates, sought out convenient places, and, in less time than is required in the relation, upward of twenty boxes were in operation, varying from the diminutive detective camera to the size of an ordinary dry goods box. Street cars and wagons rushed to and fro between the operators and the group, thus increasing the confusion, and many fleeting moments galloped by before Mr. Seavey called "All ready! Go!" and in another half-second the caps were off the lenses, the shutters clicked, the plates flashed from the boxes, and the howling mob, quieted only for a second, were shown up in miniature as the most orderly assemblage imaginable. Pan-fish and all were so idealised that there, in the sombre shadows of the stately temple of art and song, one saw a gathering representative of the refinement, intelligence, and civilisation of the nineteenth century. Ingles, Weingartner, Rombach, Munroe, Allen, Wardlaw, Kent, and many other famous photographers secured negatives, and while the band on the balcony still tooted its inspiring strains there was a general scampering for the "dark rooms" where the developments were made. The march to the Zoo then began, dozens carrying with them cameras, intending to secure pictures of the animals and birds of that famous garden."

The publication of the remainder of the proceedings must be delayed until we are in a position to have them recorded. It is to be regretted that the local papers were either incompetent or unwilling to give a fuller report than they have done.

It is stated that two reports were submitted, but there is no indication as to the nature of these reports. It is, however, customary that the reports on *Photographic Progress* during the past year be handed in sometime in the course of the first two days.

According to announcement made last year a committee was appointed to draw up such a report, Mr. J. Traill Taylor being the chairman. We learn that on the grounds of inability to confer with his fellow-members of committee—some of whom lived hundreds of miles apart—Mr. Taylor had some correspondence with the President relative to his being relieved of the duty. The President sympathised with him in his position; but, instead of allowing him to retire, discharged the other members, leaving Mr. Taylor forming a committee of one. But in the absence of this gentleman from New York, afraid that no report whatever might be forthcoming, Mr. Charles Gentile, of Chicago, was requested to fill the anticipated gap. As we are fortunate in having received advance slips of the reports of both the gentlemen named we append them, although, from the slip-shod manner in which the two daily newspapers referred to have reported the proceedings, we are in the meantime somewhat at a loss to indicate any particulars connected with the reading of these reports. But whether they were read on the first, the second, or the third day, or were not read at all, they will afford an example of the way in which two different men look at the photographic transactions of the world during the past twelve months:—

REPORTS ON PHOTOGRAPHIC PROGRESS.

By C. Gentile.

I much regret that we have not a report from the able pen of Mr. J. Traill Taylor, as I know it would have interested us and been appreciated.

As regards the progress of photography during the past year it will appear that there has not been any marked improvement to record. But let us reflect and see what has been done; for, most assuredly, there has been great progress in the spread of our art-science. Never has there been a year so prolific in the creation of photographers in America as during the past year. If we go on increasing as in the past it will not be long before the number of amateurs will outnumber the professionals. In my opinion this influx of educated men of an inquiring turn of mind will be anything but hurtful to our profession; it will assuredly tend to elevate it in the estimation of the public—a thing of which we stand in need.

One rapid stride that photography has recently taken is the use that is made of it in courts of law as a means of aiding juries to form just and correct opinions on matters that otherwise would be in doubt.

In cases of forgery, duplications of precious documents, comparisons of specimens, of textile fabrics, blood, and crystals, it is constantly used with ever-increasing advantage, and the veracity of the testimony of the expert is put beyond the question of a doubt. The detective camera has also been brought into practical use, and adds its assistance to the detection of the criminal. In jails and penitentiaries likewise the camera and photographer has penetrated, and an instantaneous likeness of each new inmate puts the prison authorities in possession of a description of a prisoner far more accurate than any verbal explanation. Many experts have been brought from the ranks of the amateur photographer because the professional photographer has not the time or means to make a study and speciality that an amateur is capable of doing.

In Europe one of the most marked improvements or discoveries has been made by Dr. Herman Vogel, of Berlin, he having discovered a process by which colours can be photographed in a manner that will render their just values more correctly than hitherto has been the case. Dr. Vogel has given his process to the world, which has been appreciated by his countrymen, who voted a handsome testimonial prize for his services in this and other improvements in our art. However, from recent European advices, it seems likely that Dr. Vogel's claims to this discovery are to be disputed, as M. Attaut Tailfer, a Frenchman, claims that he is the inventor and patentee of the isochromatic gelatino-bromide of silver plates; and, in a long discussion that occurred on the 4th of July before the Photographic Society of France, it was proved that Major Waterhouse, of Calcutta, had a prior claim, he being the first to propose colouring the film to obtain different results.

In many branches of what would be called "commercial photography" great progress has been made during the past year. I have reference to the mechanical means of rapidly multiplying photographs by means of processes known as typographical or lithographic. A process known as the ink process gives very beautiful results, being extensively used in England. We frequently receive illustrations in their journals that prove the perfection they have arrived at in this mode of producing a plate that can be employed in the steam press, as the Sprague ink photograph, which has been used for book illustrations.

We have every reason to believe that the time is not far distant when our daily papers will be illustrated by the aid of photography, for there have been many and great improvements in block work by Ives, Meisenbach, and several others well known to us.

The bromo-gelatine dry plate, as we see from the exhibition before us in these halls, has made immense strides in popularity during the past year. It is needless for me to try to say much on this subject when we have such a show before us that are facts indisputably proving the superiority of the dry plate over collodion and the negative bath, which are being very rapidly put aside by all progressive photographers today. An operator now who cannot work dry plates satisfactorily stands a poor chance of obtaining a first-class situation.

The dry plate has caused a revolution in our business in many ways. The smallest country photographers can now claim to use exactly the same chemicals as the best operator in our profession; but I would remind them of a recent remark made by Colonel Stuart Wortley, at the last meeting of the Photographic Society of Great Britain, when he said he could teach a person how to make a plate, but that to develope a plate was a *science*—a most true remark as regards the developing. The making of a really first-class plate is no easy matter, as any thoroughly conversant with their manufacture will admit.

I regret to say that during the past year we have lost several leading lights in photographic literature. I allude chiefly to the recent loss to photographic journalism of Mr. H. Baden Pritchard, who has done much for us, and I am sure his death will be a great loss. There have been several other losses of men prominent in the profession in England and other countries in Europe; but it gives me great pleasure to state that I have not to record the death of many in America.

As regards the progress of our literature it seems to be rapidly increasing; for instance, in Chicago we have a weekly and also a fortnightly published in the interest of our art.

In Europe the governments take an interest in photography that is not done in this country. The King of the Belgians has invited a congress of photographers to assemble at Brussels to take into consideration the advisability of greater accuracy in the use of terms and uniformity with regard to photographic dimensions.

In England the Photographic Society of Great Britain has accomplished something on this subject by establishing standards for screws and flanges.

It seems to me it would not be inappropriate for this Association to take steps to be represented at this congress to be held in Belgium.

Whether or not the government of the United States has been invited to take any notice of the coming congress I am unable at present to furnish any information. I know that other governments have. We are certainly interested as much as our European brethren in the proper accuracy in the use of all terms connected with our profession.

Dry-plate photography, together with the rapid increase in the number of amateur photographers, has caused the manufacturers of all kinds of apparatus to bestir themselves to endeavour to produce the most portable, elegant, and useful apparatus. During the past year many improvements have been made which are of value to us all.

Every year the artists (the painter, I mean) are becoming more closely allied. The portrait painter finds it difficult to get along without the assistance of the photographer; and I find that the more a painter knows of photography the more willing he is to leave his sitter in the hands of the photographer to light and pose his subject. He is more willing to look on and content himself with a few suggestions only, knowing that the good photographer understands the effects that can be obtained under his own skylight better than one who knows nothing about it.

I am satisfied that the demand for photography in all its branches is on the increase, and will be so.

Lastly, but not least: of the improvements that can be recorded during the past year is the great progress in illuminating the dark room of the dry-plate worker. I most thoroughly endorse Mr. Debenham's system of orange and green glass as a means of satisfactorily lighting the dark room.

By J. Traill Taylor.

Photography advances with such imperceptible strides as to render it somewhat difficult to indicate definitely the progress it has made within a circumscribed period, more especially when such period embraces the comparatively brief span of one year. While the past twelve months have not been so fruitful in invention or discovery as to cause that period to stand out in contrast with others, neither have they, on the other hand, been characterised by stagnation.

During the past year innumerable printing processes of a mechanical description, or involving the use of printers' ink, have been invented, patented, or published. Of these, some have reference to the production of intaglio surfaces for employment as in copperplate printing; others—and these the most numerous—come under the category of relief or surface blocks for printing in conjunction with type.

There is another process to which none of these distinctions apply, inasmuch as it is neither an intaglio nor relief process. It has not been patented or published, but is worked as a secret process. And yet it is in place to refer to it here, because during the past year it has been selected as *the* process apparently best adapted for preparing the illustrations of the leading European photographic journals. From the brief description which I shall give, its character and, possibly, its *modus operandi* will be perceived. To commence at the end: the printing is executed at the lithographic press from a transfer laid down upon a lithographic stone, which is smooth or polished—not grained. And yet the print possesses a fine stippled grain similar to a chalk drawing or a print from a grained stone. From this any one conversant with the process of lithographic printing will necessarily infer that the granularity has been imparted at a stage prior to that of placing the transfer upon the stone. A film of bichromatised gelatine supported upon paper, glass, metal, or any other substance more convenient is exposed to light under a negative. It is now submitted to the action of chemicals, by which granularity is imparted to the surface, although the gelatine film may be so prepared as to possess within itself the requisites for imparting the stipple. In an outline sketch like the present, however, it is unnecessary to describe the means employed for producing this indispensable effect—the more particularly as they are, doubtless, known to most of those for whom this subject possesses interest. The requisite granularity of surface having been obtained, it is rolled up with transfer ink, and an impression being taken on transfer paper is conveyed to the stone, from which impressions are obtained in the usual mode. From such experiments as I have made I am enabled to say that the fineness or coarseness of the grain is under the complete control, and ranges between the most delicate touch of a blacklead pencil to the coarse, granular texture characteristic of the large portraits of actors and others utilised as public show-bills.

Desirous of ascertaining the possibility of applying this process to the production of surface blocks, I laid a transfer upon a polished zinc plate, etched it in such a manner as not to undercut the delicate stippled grain, and in this way produced a block which was capable of being printed when surrounded by type. This, however, is a deviation from what I commenced with, which is that the process as printed from lithographic stones is an accomplished fact, whatever may be the nature of its details, and is one which, from now being extensively made use of by European, and especially by English, journals is worthy of notice.

No topic has of late engrossed more attention than that of the illumination of the operating-room. The yellow light by which wet collodion operations could be safely conducted was found totally inadequate for gelatine plate manipulations, and was superseded by light of an intense, deep, ruby colour. In a physiological point of view this was found to be productive of effects positively deleterious to the eyesight in some cases, and inconvenient in others. Hence a reaction set in and the question was propounded—"Which is the light that produces the least amount of action on the sensitive plate combined with comfort to those in the dark room?" Mr. W. E. Debenham, a professional portrait photographer, of London, constituted himself the champion of reform. He found that perfect safety to the plates, together with comfort to the eyes and a resulting light of a character which, by contrast with others, may be termed a "very subdued white light," was obtained by interposing between the lamp and the manipulating bench a compound layer composed of green glass and yellow paper. Two thicknesses of paper of a deep canary colour, along with a plate of green glass or of gelatine or paper stained of a peculiar green colour, have in my own case been made to supersede a deep ruby glass with much comfort and satifaction. The particular tints are of importance.

But the special advantages of green light as a useful source of illumination in the dark room are not now pointed out for the first time. In January, 1870, an American gentleman, whose name is as much honoured in Europe as in the United States (for science is of no nationality), strongly recommended the substitution of green glass, pure and simple, for the orange glass hitherto employed in dark-room illumination; and this recommendation of Mr. Matthew Carey Lea was enforced by arguments deduced from his own experience of its use. The light he employed was gas, and the green glass was neither the darkest nor the lightest kind, but that of an intermediate shade, care being taken that it was not of a bluish-green. Such a light, while possessing all that comfort and safety for the eyes claimed on its behalf at the time by Mr. Lea, was safe for collodion plates only, and this when the light was not too powerful. The addition of the yellow paper referred to appears to fulfil all the requirements of the present time. Even when it may prove inconvenient at once to remove the red glass from a window or lantern, a marked improvement in the quality of the light will be immediately perceived by the addition of one thickness of yellow paper.

The subject of increasing and reducing the intensity of gelatine negatives is one that has received and is still receiving much attention. As regards intensification: chloride of mercury followed by other agents still enjoys popular favour, notwithstanding many recorded cases of deterioration. The first action of chloride of mercury upon a negative, as we all know, is to turn it black. If the action be arrested at this stage by copious washing the image appears to be permanent. Certainly I have found no change in some that were treated in this manner about nine years ago, while in connection with other negatives treated with this salt, combined with iodides and other preparations, I have not experienced the same immunity from change.

A method of adding iodide of mercury to the developer, as suggested by Mr. Henry J. Newton, by which an increase of intensity is obtained by the developing operation, is a fitting subject for—and will doubtless receive—consideration by the members at this Convention. A solution which is at once a decolouriser and, with the addition of a few drops of silver, an intensifier was introduced by Mr. B. J. Edwards just in time to permit of its being alluded to in my *Report on Photographic Progress* last year. It consists in adding to the usual clearing solution of citric acid and alum a quantity of protosulphate of iron in the proportion of about one-third more than the combined weight of the other two ingredients. When employed without any nitrate of silver it decolourises a yellow negative; with silver it intensifies the image. Since the last Convention it has been much tried, and enjoys popular favour. Pyrogallic acid, as a reducer of the nitrate, is also now being employed. These, it will be observed, are analogues of the methods long since suggested for collodion intensification. I fail to discover among my negatives any which have faded after having been treated first with chloride of mercury and then with diluted ammonia, or old cyanide fixing solution nearly saturated with silver. Exceptional care was taken in the washing of these.

Reducing intensity may be effected by a variety of processes. Those only which are of recent introduction will be here noticed. Mr. A. L. Henderson has found that the fumes of cyanide of potassium, acting upon a gelatine negative to which air has free access, will effect a gradual reduction of its density. This reducing action is not a rapid one. It may be safely predicted that a method of reducing intensity proposed by Mr. E. Howard Farmer will prove to be *the* process of the future. If a solution of ferridcyanide of potassium (red prussiate) be applied to a gelatine negative the silver forming the image becomes immediately converted into ferrocyanide of sliver, to remove which all that is necessary is to apply hyposulphite of soda. Mr. Farmer mixes these together in the following proportions:—An ounce of the ferridcyanide is dissolved in a pint of water, and when about to use it a few drops are added to a solution of hyposulphite of soda of the same strength as the other. When the negative is immersed in this a gradual reduction of intensity takes place; for as the silver forming the image becomes converted into the ferrocyanide of silver it is immediately dissolved by the hypo. I have tried numerous experiments with this system of reducing negatives, both wholly and locally, and beg strongly to bear testimony to its merits. Its description will suggest the somewhat analogous solution of iodine in cyanide of potassium; but the latter is unmanageable and dangerous by comparison.

Much ingenuity has been displayed in the devising of instantaneous shutters, into which have been imported numerous mechanical appliances. Portrait photographers require, however, not so much a shutter giving instantaniety of action as a prolongation of the exposure at will. Without intending any slight to the many ingenious inventions designed to effect this end, I may adduce as an example of one of the latest that recently introduced by Mr. Cadett—the gentleman who, it will be remembered, was the first to apply the pneumatic principle to exposures in the camera. This most ingenious effort of Mr. Cadett's may be described as a square cap, which is fixed upon either the inner or outer end of the lens. A very fine piece of rubber tubing is attached to the side, the other end of which terminates in the well-known pneumatic ball. Upon pressing this a tiny rubber bellows concealed in the body of the cap actuates a lever, by which a sliding shutter working between guides immediately darts upwards, leaving the lens uncovered for either a fraction of a second or a period that may be prolonged into minutes according to the nature and duration of the pressure upon the rubber ball.

Shutters suggest lenses. Since the Convention of last year no new form of lens has been introduced; but immediately before that meeting an amateur optician, Mr. Thomas Furnell, devised a form of combination, which from its character appears to hold out a promise of good so soon as it is introduced by the manufacturing opticians. Although it cannot be said to possess either novelty or principle, or, indeed, anything startling—inasmuch as it is only a slight departure from what has been previously effected—yet curves other than those hitherto adopted have been imported into it, and, while there is no difficulty in its construction, it defines sharply over a moderately-large field. It is a triple lens—a class, by the way, which has been out of favour for several years. Its front lens is achromatised. The centre element is a single lens of flint glass, double concave, and its back a plano-convex of crown glass.

Nothing has of late transpired in connection with negative gelatine emulsion calling for special mention, unless it be the fact that the value of an addition of iodide to the bromide is more and more fully recognised. The preparation of paper, opal plates, and plain glass plates with gelatino-chloride emulsion is now an established branch of commerce—at least in certain parts of the world. For producing enlargements by the lantern the application of emulsion to paper offers exceptional advantages, for the operations may be conducted quite independently of daylight. Opal pictures, either enlarged or printed in the frame, possess a peculiar charm; while, for lantern transparencies, a point of value is found in chloride emulsion, as with any given class or brand of plate any desired tone—from the warmest red to the coldest black, including sepia, brown, and purple—can be obtained at will by the action of the developer alone.

It is several years since eosine was suggested as a substance which, when added to collodion, tended to give a more truthful representation in light and shade of the colours of nature. It is pleasing to be able to report that Professor Vogel has of late made some further advances in this department of photography.

Among the deaths of those more or less known in the ranks of photographers may be noticed that of Mr. Codman, of Boston, and in the Old World those of Mr. H. B. Pritchard (of the *Photographic News*), and the Rev. F. F. Statham, who was the President of the South London Photographic Society since the period of its organisation.

There are many other subjects of a less important description which have transpired in the photographic world; but to even refer to them all would unduly lengthen this communication.

RECENT PATENTS.

APPLICATION FOR PATENT.

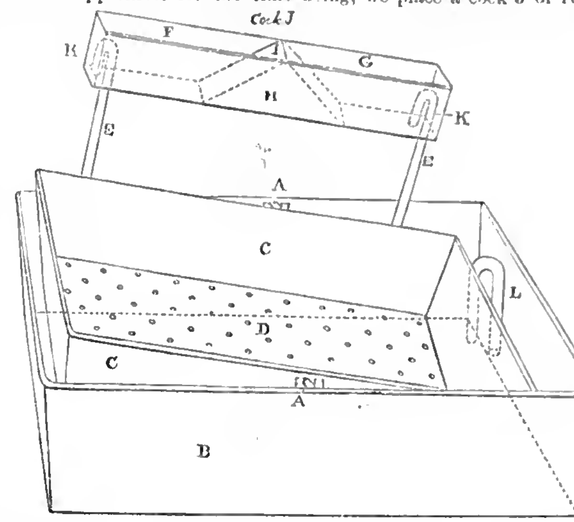
No. 10,970.—"Enamelling (as termed in photography) Surface-Coloured Photographs, whether the same are Coloured or Painted in Water or Oil Colours." Frederick Safe, photographer, 28, Grove-road, Holloway, N.—*Dated August* 6, 1884.

Apparatus for Washing Photographs.

Complete specification. By Abel McDonald, Penrith, and Thomas Williamson Kendall, Cockermouth.

In washing photographic prints it is very desirable to give them a good shake up, but without crushing or tearing them, both to prevent the prints sticking together and to cause the water to thoroughly circulate over their entire surface, and thus wash out all the hyposulphite contained in them.

We accomplish this periodic shaking in the following manner and with the following apparatus, namely:—Pivoted on a trunnion or bearing A on two opposite sides of the main trough B, and so that it is free to oscillate through a considerable arc, we place a second tank C with a perforated bottom D. In this tank the photographs to be washed are placed, together with a quantity of water. Fixed to or supported in sockets or standards E on this oscillating trough and a trifle above it, and divided over the axis of the trunnions aforesaid into two divisions, F and G, we fix a trough H having a double slope I in the centre as the division. Into this, over the point of double slope, so as to run mostly or entirely into whichever division is uppermost for the time being, we place a cock J of running



water, and in each division of this trough at the extreme end we place a syphon K K, emptying into the main trough, preferably through standards E E as shown.

The mode of action is as follows:—The washing trough or box resting on the main trough at one end and on the trunnions in the middle, the upper end of the main trough H fills by reason of the running water till it overbalances, and causes the washing trough C to turn on its trunnions. The water now runs into the other upper trough, the first trough slants the opposite way to what it did before, and the syphon being at its (now) lowest end, the water overflows to the top of the syphon, and is then immediately emptied by the syphon. The water running into the other upper trough in time nearly fills it in turn, and the whole turns over into the original position and remains so till a a like operation takes place on the other side, when it again counterbalances and so on. The water continually running in from the syphons would soon fill the main troughs, so a syphon L is placed on the main trough, so that it shall be periodically emptied entirely or in part. It will be obvious that this idea of two syphons, water supply and oscillating tank once suggested, numerous modifications could be made to act on the same principle.

The main principles of the invention being the supporting of the washing trough on trunnions, and supplying it with separate ports, one on each side, which, being filled and emptied alternately, keep up an intermittent see-saw action in the perforated tank, which action causes the water to rush up through the perforations and thus gently move the prints in a wave, thus separating and moving them very quickly without the crushing or tearing action so prevalent in most tilting machines where the prints all wash to the lower end.

Having now particularly described and ascertained the nature of our said invention, and in what manner the same is to be performed, we declare that what we claim is:—

1st. The divided trough H with a syphon at or near each end in combination with a source of water supply J, and a pivoted washing trough D in an outer trough or reservoir B, substantially as and for the purposes described.

2nd. In a photograph washing apparatus the pivoted trough *c* suspended in water receptacle B having perforated bottom and automatic means for periodically tilting it, whereby the water is caused to rise through the perforations and gently stir up the photographs.

3rd. In a photographic washing apparatus the application of the constant water supply to first actuate the stirring or shaking mechanism and then to fall into the washing apparatus and be used for washing, substantially as described.

Our Editorial Table.

The Patent Simplex Slide and Reversible Camera Back.

We have had submitted to our inspection by Messrs. John and Alfred George Hopkins, the patentees, a model of this apparatus, which was described in the patent column in our issue of June 6th last. The chief feature lies in the plate carrier and the method by which the plate is placed in position for exposure in the camera. The back of the camera closes with a door, rendering it perfectly light-tight. The carrier consists of a plain wooden envelope, into which the plate slides in a frame that completely closes the aperture by which it is inserted, and this carrier is attached to the top of the camera by suitable fasteners. In order to focus the picture, the door of the camera back is opened and the detached focussing glass placed in position; when the operation is complete the ground glass is removed, the door closed, and by means of a rod inserted in a screw hole in the upper part of the carrier the frame containing the plate is pushed into the position previously occupied by the focussing-glass, and after exposure withdrawn in the same manner. The entire absence of hinges and dangerous joints seems to promise immunity from any chance of light reaching the plate at any stage of the process except during exposure; and the general construction is so simple that the slide may be constructed at a very small cost.

How to be a Successful Amateur Photographer.
By W. J. Lancaster.

Still another guide for beginners in photography—this time issued by the energetic Birmingham firm of opticians and manufacturers of apparatus. It consists chiefly, of course, of a description of the principal articles supplied by Messrs. Lancaster and Son, supplemented by a variety of useful and practical information, which, combined with its small cost, will recommend it to a large section of intending amateurs.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
August 19	Bolton Club	The Studio, Chancery-lane.
" 20	Photographic Club	Anderton's Hotel, Fleet-street.
" 21	London and Provincial	Masons' Hall, Basinghall-street.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on Thursday, the 7th instant, the chair was occupied by Mr. W. H. Prestwich.

Mr. J. B. B. Wellington mentioned that he had tried the effect of Mr. Farmer's ferridcyanide reducer on over-printed albumen proofs, and found that it answered perfectly in lightening them; whilst he thought that the tone was a little improved, being made warmer.

Mr. A. Cowan had also used the same means for reducing chloride transparencies with similar results.

A question from the box was read:—"The querist, having obtained fog in a dark slide in which leather was used, is desirous of knowing the chemical composition of leather."

Mr. W. E. Debenham said that when fog was attributed to the leather or leather cloth of dark slides it was supposed that the pigment or medium used with the pigment was the cause of the mischief.

Mr. W. H. Ashman had found that fog had arisen from storing plates in a box that had been coated with spirit black to which a certain amount of castor oil had been added. He also stated that the emanations from pine would cause fogging in plates left in a box made of that wood.

Mr. Cowan showed a series of transparencies printed from negatives taken by him during the photographers' outing on bank holiday.

A vignetting arrangement of American construction was shown and explained to the meeting. It was what was known as "Singhi's," and consisted of a light frame just fitting on to the ordinary printing frame, to which it was held by an india-rubber web passing over the back of the press at either end. The front of the frame was a sheet of fine, smooth millboard, with a central opening and two strips of the same millboard running down the sides. These strips serve to keep in place another piece of millboard, but allow motion when required. This second front of millboard was similarly fitted with strips, but these strips were placed in the contrary direction from those in the undermost sheet. A third piece of millboard, sliding on the face of the second piece, could, by means of the slips mentioned, be adjusted in any position in the same manner as a lens in a camera furnished with vertical and horizontal sliding movements. The piece of millboard mentioned as the third piece was the one which actually performed the vignetting, and a set of these, with openings of different sizes, was supplied with each frame. If in order to make the vignetting more gradual it was desired to raise the opening, so as to make it more distant from the negative, this was accomplished by inserting a strip of wood at either end or both ends of the vignetting arrangement, between the latter and the front of the printing-press.

Mr. Cowan mentioned having shown a similar arrangement some nine months previously, but it was stated that Singhi's apparatus as now shown had been in use in the United States some time earlier than that.

Mr. Debenham had for many years used an arrangement in many respects similar, but he thought more convenient, as in his the fronts did not extend beyond the edge of the printing-frame, and so did not require additional space at the printing light. He would bring one to a future meeting.

Mr. Ashman had shown in his lecturette *On Printing* some vignetting forms made of what was known as "empire cloth." The great secret of obtaining soft vignettes was to have a small opening and to keep it at a distance from the negative.

Mr. W. Coles, referring to Mr. Wellington's experiments in removing green fog with Mr. Farmer's ferridcyanide reducer, stated that his experiments in the same direction supported the conclusions of Mr. Wellington.

Mr. W. Turner showed some paper negatives produced by using drawings or tracings as originals in the pressure-frame and printing by contact upon salted paper sensitised with nitrate of silver and fixed in an old hypo. bath. Prints from these paper negatives were also shown. These prints were by the ferro-prussiate or blue process, such as will be found described on page 756 of our last volume.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The annual excursion and pic-nic of this Society took place on Thursday, the 10th July, when about sixty ladies and gentlemen visited the grounds of Arniston House by the kind permission of R. Dundas, Esq. On arrival luncheon was served, and this was followed by the company being photographed in a group under the fine old leaning larch tree, which, as indicated by the nurseryman's bill (still preserved), was planted in 1735.

There was an interesting series of competitions for both sexes. In the following list of successful competitors the name of the donor and the nature of each prize is placed in a parenthesis:—High leap—1st, Mr. Calder (handsome pipe, Mr. Bertram); 2nd, Mr. M'Kean (series of twelve carbon prints, Mr. Dougall). 100 yards race for ladies—1st, Miss Mary Tunny (parasol, Mr. Bertram); 2nd, Miss Tunny (twelve carbon photographs, Mr. Dougall). 150 yards ditto—1st, Miss Pearson (hand-bag, Mr. Crighten); 2nd, Miss Raynor (box of biscuits, Mr. Middlemas). 150 yards race for gentlemen—1st, Mr. Calder (illuminated album, Mr. M'Kean); 2nd, Mr. M'Kean (box of biscuits, Mr. Middlemas). Barrow race—1st, Miss Taylor (graphoscope, Mr. Turnbull); 2nd, Mr. Dougall (pair of skates, Mr. Johnston). Hopping race—1st, Miss Raynor (album, Mr. Cox); 2nd, Miss Pearson (one dozen photographs, Mr. Dougall). Photographic competition—Best "Bit" taken in the Ground at Arniston—1st prize, Mr. Briglemen (one bottle fifty years' old brandy, Mr. Baillie); 2nd prize, Mr. M'Kean (opera glass, Mr. Wardale).

A small string band discoursed excellent music during dinner, which was served at two o'clock, the President, Mr. William Neilson, occupying the chair and proposing the usual loyal toasts.

Mr. William Dougall gave "Prosperity to the Society, and the Health of the President," which was happily replied to by Mr. Neilson. Mr. Brodie gave the "Council and Office-bearers," replied to by Mr. Bashford, Hon. Secretary. Mr. John Gardner proposed "The Committee for the Pic-nic," coupled with the name of Mr. Thomas Wardale, the convener, who suitably replied. Mr. J. G. Tunny proposed the "Health of Mr. Dundas," of Arniston, who had personally welcomed the Society to his grounds and granted them every liberty and accommodation. Mr. Dundas said he had studied photography thirty years ago under Mr. Tunny, and was much pleased to see the Society at his place. Mr. Crighton gave "The Ladies," which was replied to by Mr. Scott.

LEEDS PHOTOGRAPHIC SOCIETY.

The ordinary meeting of this Society was held on Thursday, the 7th inst., —Mr. J. W. Ramsden in the chair.

After the confirmation of the minutes the subject of outdoor excursions was introduced by Mr. S. A. Warburton; and it was resolved, on the motion of Mr. Marshall, seconded by Mr. F. W. Branson, that the Committee be requested to arrange for outdoor excursions, to take place not less than once a month nor more frequently than once a fortnight. The announcements of the excursions are to be made on the Society's board in one of the windows of the Philosophical Hall, and kept two or three weeks in advance —the place of meeting and time to be arranged as best suits the excursion.

It was then arranged that an excursion should be made on Saturday (tomorrow), the 16th inst., to Meanwood Valley and Adel Moors. The party to meet at the "Three Horseshoes," Headingley, at 2.30, p.m.

Mr. F. W. Branson called the attention of the meeting to some chemical reactions involved in the treatment of a bleached image (produced by bichloride of mercury) with a half-saturated solution of recrystallised sodium sulphite, as mentioned and commended in The British Journal of Photography of July 25th. From experiments made the following facts were deduced:—

1. That a solution of bichloride of mercury is not reduced to calomel, nor is a sulphide formed when cold solutions of bichloride of mercury and recrystallised sodium sulphite are mixed.

2. That freshly-formed and washed silver chloride is not blackened, but is dissolved to a very appreciable extent, by a solution of sodium sulphite of the strength recommended.

3. That mercurous chloride (calomel) is readily blackened, with production of a sulphide of mercury, by a solution of sodium sulphite.

It was explained that the white image caused by the action of a solution of bichloride of mercury consisted of both mercurous chloride (calomel) and silver chloride, and that when sodium sulphite solution was added the silver salt dissolved, and the mercury salt became blackened to form the photographic image. The removal of the silver salt probably explained the small degree of intensification given by this method, as contrasted with some other methods in use. That a strengthening of the image does occur is certain, and that no part of the plate is discoloured except the photographic image constitutes an important advantage. It was also pointed out that a fact of considerable practical importance remains to be proved, namely, whether a sulphide by mercury, as produced by the action of sodium sulphite, &c., or an oxide, as yielded by treatment with ammonia, gives the most permanent negative.

After a short discussion on Mr. Bransen's communication in which the Vice-President, Messrs. Teasdale, Thornton, Wilday, &c., took part,

Mr. W. L. Wilday passed round some prints on ferro-prussiate paper, and recommended the process as very useful to amateurs as well as professionals in a number of ways. He (Mr. Wilday) gave the following details as to his mode of working the process:—

Ammonia citrate of iron	15 drachms.
Distilled water	8 ounces.
Ferridcyanide of potassium	10 drachms.
Distilled water	8 ounces.

Mix the two solutions and keep in an opaque bottle. Take unglazed paper of a fine grain and damp the sheets you propose to sensitise with a sponge or rubber brush; float the solution over the paper as evenly as possible, and hang to dry in a darkened room. Do not prepare a larger quantity than you are going to use shortly, as the paper becomes slower by keeping. When printing, expose until the shadows assume a strong, metallic, grey colour, and detail begins to be lost. Wash well in cold water until, when held up by the corner, the drip from the print shows no yellow tinge. If it be desired to write on the print use a saturated solution of washing soda as ink and a clean steel pen to write with.

Mr. Thos. W. Thornton (Hon. Secretary) then exhibited samples of Willesden paper, and spoke of the many uses to which it might be put by photographers. Being perfectly watertight, with a cake of marine glue and a sheet of Willesden paper a tourist could easily make dishes for developing and fixing when away from home, or by its aid a temporary dark room could be readily formed. He said that by the kindness of Mr. W. M. Ashman he had received samples of the vulcanite fibre, respecting which inquiries had been made at the last meeting. These he passed round to the members, saying he had been experimenting with them and found that it was practically unbreakable, and could be worked in almost any conceivable manner. He had grooved, planed, turned, sawn, and bored it with great ease, and he was of opinion that it might be used with advantage in place of ebonite for making shutters, &c.

Mr. Branson said he had used the fibre and found that it was affected by damp.

The Hon. Secretary exhibited a changing-bag for dry plates that he had had made after a design by Mr. W. Brooks, and used every day during a recent tour.

The meeting then proceeded to the examination of a number of transparencies shown by Mr. W. Teasdale by means of the sciopticon lantern. Mr. Teasdale's arrangements and portable screen were very much admired.

Correspondence.

ON PHOTOGRAPHING THE OUTLINES OF COASTS AND HEADLANDS FROM THE SEA.

To the Editors.

Gentlemen,—There is a remark in an article by Professor H. W. Vogel, in your last issue, which might deter many from attempting deck photography, insomuch that he insists upon the stoppage of the engine in order to get a sharp picture. In some cases this may be advisable—if, for instance, the resulting picture had to be enlarged.

But for ordinary pictorial work it is by no means necessary; and, if the shutter be quick enough and not influenced by the wind, as Herr Vogel's was, good views may be taken. I have taken several lately covering a whole-plate, and in some cases cannot distinguish at first sight those taken from a steamer at full speed from those taken on *terra firma*.

I note, also, that the stand used by Professor Vogel seems identical to that patented and exhibited some time ago by Mr. Thompson, of this city.—I am, yours, &c., J. H. T. Ellerbeck.

Liverpool, August 12, 1884.

THE SODA DEVELOPER.

To the Editors.

Gentlemen,—Seeing in your Journal of the 1st instant a very strong recommendation of the washing soda developer, by Mr. A. F. Genlain, I have tried a few plates with it and find the negatives produced to be of good printing quality, though of a very peculiar colour; also the working to be well under control.

But will Mr. Genlain tell us how to avoid frilling? He apparently prepares his own plates especially for the purpose with chrome alum in the emulsion; but what are the thousands of amateurs *and* professionals to do who work with commercial plates?

I tried soaking the plate in chrome alum before developing, without any improvement as regards frilling, though the green colour of the negative was less decided. Possibly in cooler weather this trouble might be reduced to a minimum.

There are, no doubt, several who have been trying this developer, and it would be interesting to know whether they have met with the same difficulty which I have. I may mention that I used the plates of two well-known manufacturers, which have never in my hands shown any sign of frilling with sulphite and pyro. or with ferrous oxalate.—I am, yours, &c.,

Woodley-hill, Reading, August 11, 1884. Charles Stephens.

Notes and Queries.

"Is there any public teacher of photography in London?—B. P."——To this we reply that at the Polytechnic Christian Institute, 309, Regent-street, photography is taught under conditions which may doubtless be obtained on application to the Secretary.

"Novice" inquires:—"If, instead of getting up a club or subscription for oil paintings, I get up a raffle or a drawing, the prize or prizes to be tickets entitling the winner to an oil painting of himself or herself, would there be anything illegal about it, or anything at all likely to bring down the authorities upon me about it? If you can give me your opinion as to the legality of the above affair I would esteem it a favour."——Will some reader versed in the laws which apply to art unions and lotteries please respond?

Unger and Hoffmann (Dresden) writing with reference to our article *On Albumenising Paper* [page 370, *ante*], say that in their experience "the preparation of albumen paper must and can be effected by means of *fermented* albumen; but it must never be in a state of putrescence, because such almost invariably produces in summer the so-called 'blisters;' and, further, the operation is so disagreeable that the workman can scarcely endure the smell. For this cause we have adopted a new method, which excludes the formation of blisters, produced by putrified albumen, and which does not cause any of the disturbances occasioned by fresh albumen." A specimen of the paper accompanied the foregoing letter.

Pembroke Marshall inquires:—"1. Is a high-priced lens considered perfect that has bubbles in it?—2. Have the majority of such lenses, by manufacturers considered first-class, bubbles, or are the latter exceptional?"——In reply: 1. No lens can be considered "perfect" that contains bubbles or any other imperfections in the glass.—2. No first-class manufacturers will issue lenses containing bubbles. In former times, when it was much more difficult to obtain good optical glass than is now the case, defects of the glass mentioned, together with tears and striæ, were not unfrequently to be found in otherwise good lenses; but makers of reputation—and, indeed, of no reputation at all—never now employ glass possessing defects of this nature. At the same time, it must be admitted that defects in glass are of less consequence in photographic lenses, especially those of large dimensions, than in any other optical instruments which necessitate the employment of an objective.

R. S. says:—"I have read your article *On the Economic Production of Cold* in last Journal with special interest. You say that certain bodies when added to the nitrate of ammonia increase the intensity of the cold produced. I have read somewhere that if twenty parts of nitrate of potash be mixed with eighty parts of nitrate of ammonia a degree of cold is produced equal to eighty-seven degrees of Fahrenheit. Now, what I wish to know is this—after these salts have thus effected the desired end by producing the cold, will they not after being again crystallised act in the same manner as before, seeing that no chemical change can have been produced in either of them by the mere act of being dissolved? and, if such be the case, will not the end of economy be obtained in greater perfection by this addition?"——We reply that although the chemical constituents of the two salts named are still present, yet by their having been dissolved in presence of each other a molecular change has been induced, double salts having been formed. These double salts do not possess the same properties as their primary constituents. This is a matter which can be easily verified by our correspondent.

"An American in England" wishes to know if there be any chance of our giving a report of the transactions of the Annual Convention of the Photographers' Association of America. This Convention, he explains, is one that is composed mainly of professional photographers, although there are a few amateurs to be found among them.——We reply: In another page in the present number will be found a report of a portion—we would fain hope a very small portion only—of the transactions of the three days' meeting. But seeing that, according to the report, the social appeared to predominate over the technical proceedings, it may be that there will be less of a solid character resulting from the meetings than we might have hoped. Our present correspondent, "An American in England," is thanked for the kindly nature of his expressions regarding this Journal, and especially for the packet containing samples of the best representative dry plates of American manufacture. When he and his friends favour us with their promised visit we shall not only, in all probability, be able to show them, upon these very plates, negatives of the spots in the vicinity of London which they desire to visit, but also have a small party of kindred spirits organised to accompany our esteemed friends from the New World on some of their intended local photographic excursions.

Exchange Column.

No charge is made for inserting these announcements; but in no case do we insert any article merely offered for sale, *that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a* nom de plume *be thought desirable), otherwise the notice will not appear.*

I will exchange a Ross's *carte* lens, four and three-quarter inch focus, for a sixteen-inch focus triplet by a good maker. — Address, W. Bray, Sidmouth.

I will exchange a half-plate camera, double swing back, three double slides, folding tripod, cost £9, for a 12 × 10 camera, also Ross's *carte* lens.—Address, 7, Abbeygate-terrace, Colchester.

I will exchange a Dallmeyer's No. 2B patent and a Ross's No. 1 universal for a Dallmeyer's No. 2A or a Ross's No. 3 rapid cabinet lens.—Address, W. Dakin, photographer, Nether-edge, Sheffield.

I will exchange a good whole-plate portrait lens, three inches in diameter, very rapid, for a Ross's rapid symmetrical or a Dallmeyer's rectilinear, not less than half-plate.—Address, A. F. Clark, Padanarm, Forfar.

I will exchange a whole-plate "J. S." portrait lens, complete, with stops, in perfect condition, cost second-hand £5, for a Lancaster or other outdoor apparatus; or offers.—Address, E. A. B., 10, Wellington-street, Gloucester.

I will exchange a Kinnear camera, 10 × 8, and a half-plate portrait lens, by Squire, for a whole-plate universal camera and small carriers; a Jamin's portrait *carte* lens; and a Grubb's half-plate view lens, for studio accessories.—Address, Fritz Camera, 41, High-street, Sydenham, S.E.

Answers to Correspondents.

☞ Correspondents should never write on both sides of the paper.

Photographs Registered.—

Herbert Henry Dunn, Newport, Lincoln.—*Photograph of Sunset over Lincoln.*

Frederick John Skill, Exchequer Gate, Lincoln.—*Photograph of Lincoln from Panwick Hill.*

William Rochard, Sea View-terrace, Bagillt, North Wales.—*Photograph of Interior of St. Mary's Church, Holywell, North Wales.*

Patrick.—You will find an article on the subject on another page. Take the practical hint there given.

T. Pinder.—You had better communicate with Mr. Philip Magnus, Secretary of the City and Guilds of London Institute, Gresham College, E.C.

D. D.—The particular glass in question may be obtained from Messrs. Chance Bros., Birmingham, or retail from Messrs. G. F. Williams and Co., 36, St. Martins-lane, W.C.

B. Dalton.—The cause of the matt varnish having dried transparent is that you have warmed the plate. All matt varnishes must be applied cold or they will become transparent when dry.

W.—You will find articles on the subject of cloud negatives and their uses on pages 552, 567, and 661 of our last volume. These will give you the desired information. See answer to "Graver" on photographing on wood blocks.

H. J.—To prepare the glass plate for receiving enamel collodion, let it be well rubbed with powdered French chalk. The enclosed print is a creditable specimen of work. Single landscape lenses are best for this class of subject.

G. M. J. B.—1. It is not an article of commerce at present; hence you will have to construct the apparatus for yourself.—2. They are for different purposes. The second is more suitable for small prints and limited numbers than the former.

W. G. Biggs.—The best plan is to write the name of the subject neatly with black varnish on the bottom of the negative; it will then appear white in the print. Of course you understand that the writing must be done backwards, so that it may read right in the prints.

I. I. I.—There is no advantage in using the alum bath stronger than you have been doing. Chrome alum is supposed to render the gelatine harder than common alum; but we see no advantage in the latter over the former for your purpose. Besides, it will slightly discolour the paper.

G. O. Mountain.—The picture is very good, but we have seen some of the same subject that have been considerably better. They were taken from nearly the same standpoint as yours. The lens appears to be a fairly good one, but it is deficient in marginal definition. Possibly a small stop will remedy this.

Graver.—We are unaware how the particular specimen you forward was produced; but the carbon process is capable of producing very successful prints on wood blocks if a suitable tissue be employed. This should be one that contains a maximum of colouring matter and a minimum of gelatine, so as to yield as thin a film as possible when finished.

F. A. Wiltshire.—The prints forwarded are collotypes. They are produced in Germany at a very cheap rate by machinery. You will not be able to get them produced in this country, even wholesale, for anything like the small price you paid, retail, for these. Machined collotypes—judging by any we have seen—are not to be compared with those produced by hand by a good printer.

Z. A.—The sample of paper forwarded certainly smells very offensively; but we have met with some that was much worse. If your employer do not mind its being used, we do not see that you should object. He is the man who is responsible if the prints fade, and not you. It is by no means proved that all paper which smells offensively yields prints which will of necessity fade rapidly.

Puzzled.—If the lens give a sharp picture when used direct, and do not when it is used with the reversing mirror, it is clear that the latter is at fault. See that it fits quite loosely in its frame, as the slightest pressure may alter its figure. See to this, and, if you still fail to get as sharp a picture with the mirror as without it, return it to the manufacturer. The slight scratch will practically make no difference whatever.

A Collotype Amateur.—If, as you say, you are only an amateur, then your specimens are indeed very good. Your present difficulty arises from the paper you are using. The enamelled coating is not hard enough for the present hot weather. Procure another sample with a harder coating for present use, and retain what you have until the weather becomes colder, when you will find it will again work well.

Thos. A. Carter.—So far as we are aware, no optician supplies photographic lenses in aluminium mounts. No doubt any lens maker would supply them to your order; but as they are not articles of commerce, and the metal and the cost of working it is somewhat expensive, such instruments would necessarily be high in price. We have an idea that what you have seen have simply been the ordinary mounts nickel plated.

Jacobus.—By "the merest rinse" is meant that the plate should be simply rinsed under the tap for a few seconds. You appear to have been in the habit of washing for an unnecessary length of time between the development and the alum bath, and between the latter and fixing. One-third the time you have expended in the operation would be ample. After fixing, the washing must be as complete as possible, otherwise the whole of the hyposulphite of soda will not be removed.

H. R. is requested to be more explicit in giving the name of the annual, the year, and the page from which he quotes, as he has got matters so "mixed" as to preclude the possibility of discovering his quotation. He is also requested to address his letters to "The Editors."

C. C.—The mealiness in the prints is due to over-toning. To get them free from mealiness you must remove them from the strong bath at a much earlier stage—when they are only a very warm brown. Clearly the sample of paper you are using will not stand deep toning.

Received.—A. Pringle; J. Archer Clarke; J. Nicol, Ph.D.; Thomas Bedding; "Mahlstick." In our next.

The "Claimant."—Application has been made to the Directors of Convict Prisons by the "Claimant" that he may not be photographed before leaving Portsmouth Prison, lest the likenesses may get into the hands of a local tradesman and copies be disposed of, as was the case when he was at Millbank. The Directors have granted the application, and the "Claimant" will, consequently, not have his prison photograph taken till he reaches Pentonville.

Photographic Club.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 20th inst., the subject will be the adjourned discussion *On Printing through Coloured Media.* Mr. Wellington will exhibit a most ingenious and simple changing-box of his own construction. On Saturday afternoon an outing has been arranged to Chingford, leaving Liverpool-street Station by the first train after 2 o'clock. Meeting afterwards at 6 o'clock, at the Forest Hotel.

International Inventions Exhibition, 1885.—The following particulars have been issued with regard to the entries in the class of photography at the forthcoming International Inventions Exhibition, to be held in 1885. The exclusion of lenses from the apparatus department is due to the fact that they are classed with Philosophical Instruments in a previous group:—In Group XXIX.—Photography—there will be three classes:—Class 159. Processes and their results.—Methods of gelatine-bromide plate-making, apparatus for making emulsion, apparatus for separating the sensitive constituent, coating, drying, and packing machines, emulsion and other processes; printing processes—silver, carbon, Woodburytype, platinotype, gelatino-bromide, collodio-chloride of silver, &c.; apparatus for washing, &c., prints and negatives, methods for making photographic lantern slides. Class 160. Apparatus (excluding lenses).—Cameras, shutters, changing-boxes, slides, tents, lamps, apparatus for making enlargements, and for microphotography. Class 161. Application of photography to various purposes, typography, ceramics, relief moulds, &c.—Method of producing printing surfaces, photographic enamels, photographic printing on pottery, photographic reliefs; use of photography in self-recording apparatus, in scientific observations, &c. Educational apparatus includes appliances used in primary, scientific, technical, and artistic instruction.

Lime-Light Explosion.—The *Irish Times* of Friday last records a very serious lime-light explosion which took place on the evening of Thursday last week at the Curragh Camp:—About 11 o'clock last night (Thursday, the 7th inst.) an explosion occurred at the theatre attached to the garrison canteen. Mr. Frank Montreal's company had been playing to crowded houses for some weeks, and the theatre, as a place of resort, had become very popular in the camp. Last night, as usual, the wooden building was again well filled to listen to "Maria Martin." Just as Corder shot his victim the lime light, which was being lighted for the purpose of enhancing the effect on the stage, exploded. The man employed by the company for this purpose was knocked down, and had his hand so severely damaged that it had to be amputated immediately afterwards by the Surgeon-Major in charge of No. 2 Hospital. His name is Jenkins, 1st Royal Dragoons, and on making inquiries this morning it was ascertained that he is in a very low state. The concussion, it is feared, may prove more dangerous than the amputation. The report of the explosion brought the camp officials to the building, and a scene of confusion prevailed. Every lamp on or near the stage was broken, the wings split, scenery torn, and the heroine herself was severely hurt. Many cases of severe contusion were attended by the medical officers. The explosive fluid took a zig-zag direction, and hurt some women who were in front so severely as to necessitate their removal to hospital at once. Altogether about sixteen or twenty men and women were carried out of the building in such a torn and bleeding state as to give rise to great fears.

CONTENTS.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1268. Vol. XXXI.—AUGUST 22, 1884.

ON THE CARE OF THE NEGATIVE FIXING BATH.

This title may at first sight appear a rather curious one, as it has become too much the fashion to look upon the negative hypo. bath as the one matter in connection with photography that requires neither care nor attention, but that may be left to look after itself. How many photographers, especially amateurs, pay no more attention to the fixing bath than to add a handful of hypo. when it begins to lose its power, or a few ounces of water when its quantity has become too much reduced by evaporation! We have actually seen both these operations performed upon baths in comparison with which the proverbial "bottled stout" would have appeared clear and bright.

And yet how many of these same operators would dare to take such liberties with the fixing bath for prints! The difference between the print and the negative is simply this—that the injury which is likely to arise from such treatment appeals more directly to the sense of sight in the case of the print, but is no more certain to occur than it is in the negative. The latter is, however, only the means to an end; and if it be possible to complete its production with a minimum of trouble, and in such a manner that by hook or by crook it may be made to yield a few decent prints, what matters if it deteriorate with age?

This, we venture to think, is a mistaken policy, for, in any case, if the negative be worth finishing at all, it is worth finishing properly; while in cases where large numbers of prints are required it is absolutely essential that every possible care be exercised. The dirty, brown, muddy-looking "puddles" that too often do duty for negative fixing baths can scarcely under any circumstances be expected to improve either the quality or the permanence of the negative, overcharged as they are with injurious silver compounds, to say nothing of the accumulated soakings of oxidised pyro. from innumerable imperfectly-washed plates. It is this latter cause which principally tends to produce the deep brown discolouration of the hypo.—not the mere saturation with silver, as a fresh solution of hypo., saturated with pure bromide of silver, remains clear and nearly colourless so long as the temperature be not raised much above the normal.

It may be asked, considering the cheapness of hypo.—Why employ the same solution more than once, or, at anyrate, for more than a given number of plates? The answer is simple. It is not for the sake of economy in the matter of hypo., but in the matter of silver. The quantity of silver dissolved out of a plate in fixing forms a very considerable percentage of the total quantity used in the preparation of the film, and this is too precious an item to be thrown away. If fresh hypo., however, is to be used for every plate, the cost of collecting and recovering the silver would be too great for the return; but by judiciously employing the same solution until it contains a notable quantity of silver a considerable economy both in trouble and material is effected. How to employ the hypo. judiciously and economically is what we have to point out.

In the first place, as bearing strictly upon the "care of the fixing bath," we may mention the necessity for a very thorough washing of the negative after development. A mere perfunctory rinsing under the tap is but an excuse. If after two or three minutes of such washing the negative be reared up to drain upon white blotting-paper it will soon be evident that the developer is far from having been removed. Nothing, indeed, short of a prolonged soaking will suffice; and the extra expenditure of time and trouble this involves will bring its recompense in increased clearness and brightness of the negative, as well as in the less filthy condition of the fixing bath.

With regard to the fixing bath itself: the exhibition of care should commence at the very earliest stage. Many of the samples of hypo. met with in commerce are very impure, containing most of them free acid, some few having an alkaline reaction, while all are mixed with mechanical impurities in the form of dirt. Let us commence, then, by making a saturated solution. In our own practice we place (say) seven pounds of hypo. in a large basin, pour on to it boiling water, and allow it to stand for a few hours with occasional stirring, and, if necessary, more water is added, until a saturated solution is formed and only a few crystals remain undissolved. It is now tested with litmus paper, which is nearly certain to be reddened; a solution of washing soda is made, and this is added—a few drops at a time and well mixed before each fresh addition—until the blue colour of the litmus is restored. If the sample be decidedly alkaline it should be *nearly* neutralised with dilute hydrochloric acid. On no account must the solution be employed while in an acid condition.

This matter having been attended to, the dirty-looking solution is filtered into a large, brown stoneware jug, from which the necessary quantities either for prints or negatives are poured off as required. For prints one part of the saturated solution is mixed with three, four, or even five parts of water, and when this dilute solution has served its purpose once for prints it is set aside for negative purposes.

In using the bath much must, of course, depend upon individual circumstances. In large establishments, where a great amount of work—both in negatives and prints—is done, it will be convenient to employ a fresh bath daily, consigning the old one to the waste tub. But this method will not answer for an amateur, to whom we recommend the plan of using two baths—that is to say, of using one bath until it is saturated, when it is set aside for "renovation," if that system be preferred, and replaced by another. If a considerable amount of printing be done it is probable, in the case of an amateur, that very little of the real use of the fixing bath will have gone out of it when it has served its purpose on the few prints required to be fixed at any one time, though it cannot be employed again for the same purpose. In such cases the bath may be placed aside in a special receptacle to form a stock solution for fixing negatives.

Each bath should consist of a quantity of solution considerably larger than is actually required to fill the dish or dipping bath when in use. After each day's work is finished the solution which has been in use should be returned to its receptacle and the fixing dish carefully washed. During the night any sediment will subside, and the clear solution is poured off for next day's use. In this manner and with proper care in washing the negatives it will be impossible for the hypo. solution to go very far wrong, and it will only be when it approaches saturation or its action becomes too slow that it need be discarded.

Many people, instead of discarding altogether a spent bath, prefer to "doctor" it into working order again. Others, again, imagine that a mixture of alum and hypo. possesses the power of recuperation within itself. As we have long since pointed out, alum and hypo. mutually decompose one another, and the only result of such a mixture is to set up a state of doubt as to what is really being used. That alum brings about the precipitation of the dissolved silver is beyond doubt; but if its aid be invoked it is better to apply it by dropping a crystal into the warmed and filtered bath, when a lively disengagement of gas will take place, and the greater portion of the silver will be precipitated and may be removed by filtration. After strengthening from the stock jug the bath is ready for use again. On the whole, we are inclined to doubt the wisdom or economy of the recuperative system.

THE AMERICAN PHOTOGRAPHIC CONVENTION AND ITS RESOLUTIONS REGARDING PRICES.

If the various reports from both newspapers and private individuals are to be credited we fear that the Convention of the Photographers' Association of America for 1884, held in Cincinnati three weeks ago, under the presidency of Mr. W. H. Kent, of Rochester, New York State, must take its place in history as the most unfruitful of all the conventions of which we possess any record.

Here we find a large body of zealous photographers showing their earnestness by travelling many hundreds of miles in order to learn something concerning the technics of their craft, and taking no pains to hide their feelings at the bitter disappointment experienced by them. It is said that some of the members have expressed an intention of discontinuing their attendance at these annual meetings in consequence of the scanty bill of intellectual fare prepared for their reception. A wise executive committee would have taken care to provide something more substantial for their *clientèle* than music, dancing, or a visit to the zoological gardens, even at the doubtless small charge of thirty-five cents, which, from the report in our last number, appears to have been insisted on; but, while these are in themselves most praiseworthy means of relaxation after hard work, the work itself is presupposed. Something more than a *soufflet* is necessary to keep up the strength and physique of an able-bodied man. A dessert implies a dinner, which, if not altogether omitted in this case, does not appear to have been supplied in such sufficiency as to have satisfied the requirements and wants of those who travelled so far in order to learn something. The committee probably knew or had their own ideas as to what the members of an American association had a right to expect; but we venture to say that if a similar convention of three days' duration were held in any town in Great Britain the committee of organisation would have ensured there being from four to six papers, lecturettes, or lectures daily on some topic of interest connected with practical photography.

It is quite possible, however, that, in the interests of the stock-dealers and dry-plate and other manufacturers to whom the treasury of the Association is annually greatly indebted for their liberal donations, the Committee may not prefer to encourage any counter attractions to the great display of new apparatus, which forms a leading and attractive feature of these Conventions, not to speak of the exhibition of photographs, many, if not most, of which are shown in the interests of rival dry-plate makers. It is right and proper that dealers and manufacturers should attend such gatherings to display and sell their wares, being both convenient to the photographer and profitable to the merchant; but certainly it is to the advantage of the former that he be made acquainted in the Conference Hall with matters of chemical, æsthetic, or manipulative interest; and it is the sparseness with which this element of the Convention has been supplied that has given rise to so much dissatisfaction on the part of the members.

But it may be that the Committee neglected to make provision for papers in the expectation of there being a rush of volunteers. It is, however, only a few weeks since a gentleman officially connected with a photographic society in Philadelphia, when on a visit to London, gave it as a characteristic of the American photographer that, while always ready to hear or learn, he was not equally ready to speak or communicate. This being the case, the Committee of Management of this great national organisation should have arranged for essayists and speakers months in advance of the date of meeting, and to have issued an official programme of the proceedings. In a country like America, possessing so many men of undoubted talent, one would think that the difficulty should be in making a proper selection in the midst of such an *embarras de richesses.*

We observe that a large portion of the brief period devoted to the discussion of photographic topics was taken up in a consideration of the prices which photographers ought to charge for their work. The absolute impossibility of arriving at any definite determination in a question of this nature is illustrated in the case of the city of Chicago, in which low prices, unfortunately, appear to prevail. In that city is a certain photographer who alleges that he alone of the fraternity there takes cabinet photographs of a high class, into the truthfulness of which assertion it does not concern us here to inquire. Upon a resolution having been adopted in the Convention to charge hereafter eight dollars per dozen for first-class cabinet portraits, five dollars for second-class, and three dollars for third-class pictures, this photographer—who designates himself "the Dictator"—promptly issued a message to the Convention, relative to this resolution (a copy of which we have received) as follows:—

"Please do not include Chicago photographers in your resolutions in regard to advancing prices, as *I will not* permit them to advance. I will make first-class cabinets at three dollars, your resolution to the contrary notwithstanding. No second-class in mine. Knowledge makes the quality—not the resolutions of photographic conventions. In Chicago first-class cabinets are made at three, second at four, and third-class at six dollars.—E. F. Hartley."

A second communication—this being addressed to the photographers of Chicago—accompanies the one just given. In it Mr. Hartley refers to the "State Photographic Society;" and, as this document is so curious and "cheeky," we give a few extracts from it by way of enabling English readers to perceive the character of some of the difficulties that have to be encountered in an endeavour to arrive at uniformity in prices. The writer says:—

"As my name and the manner of doing business have been criticised at the meeting of the said Society, I consider it my duty to reply by circular.

"At the last meeting the subject of prices came up again, in spite of the fact that I told you it would be impossible for you to advance the price until I consented. It seems to me that you are wasting time talking of prices as long as I am not interested in your 'going up.' * * *

"One photographer said he did not consider me a competitor; that if you paid any attention to me you would never advance. If I am not a competitor why do I have so much influence? Why have I got your noses to the grindstone? Why, it would just be as impossible for you to advance your price unless I advance as it is for you to go down without starving.

"The high-priced galleries discharge their high-toned operators for lack of business, and I hire them and pay them higher wages than they ever paid the same men. I am making, and will continue to make, as fine work as it is possible for any man to make. My knowledge of photography is at least equal to any of yours, and the price has nothing to do with the quality. A man with a limited knowledge of photography could not produce fine work at $10 any better than at $3.

"Photographers outside of Chicago ask:—'Why is it that Hartley can control the prices in a city of 500,000?'

"One man said it is a good time to advance. Yes; that is so—if Hartley will head the list. But consider me a $3 man until further notice; I will let you know when you can go up." * * *

This was signed—"'The Dictator,' Hartley."

The publication of these circulars affords better than anything else a view of the difficulties which must and always will intervene to prevent an assimilation of prices for photographic work.

With regard to the resolution adopted by the Convention, another difficulty arises: certain of the members are said to charge at present little more than three dollars a dozen for their cabinets. Now, unless human nature is different in America than it is in England, such photographers will not find it an easy matter to raise their prices from three dollars to eight dollars per dozen—from twelve and sixpence to one pound, thirteen shillings and fourpence—at a bound; nor will it be pleasant for them, by retaining their former prices, to make the implied confession that their work is of a third-class order. Just fancy a convention of painters adopting resolutions concerning the prices to be charged to the public for artistic work of a certain definite size !

THE USE OF INSTANTANEOUS SHUTTERS.

Our readers need not be alarmed under the impression that we are about to enter into a disquisition upon the merits of the various shutters in the market, for such is not our purpose—the task would require a volume of large size. It was formerly said that there were more gelatine plate-makers than users, and much more truly might a similar remark be applied to inventors of instantaneous shutters. For our purpose, however, it will, nevertheless, be necessary to dwell to a slight extent upon the principles governing their action, in order to give point to our remarks.

Almost every inventor or user of these adjuncts to exposure can point to wonderful examples of quickly-taken pictures—flying birds, galloping horses, acrobatic exercises, &c., &c.—and up to that point each shutter can be said to be a success. But this, we apprehend, is not any real test of the working usefulness of a shutter. A better one would be an answer to the question—"How many failures were there for each success?"

An amateur who starts from home to do "drop-shutter" work does not generally set up his tripod if the weather be unfavourable, and no one is the worse or the wiser; but the case is different with the professional photographer who may be commissioned to take a number of pictures on a given day, and perhaps include among them a horse or two, or, maybe, a favourite dog with a few children thrown in to make a picture. If he do not like the light it is not a difficult matter to click his drop shutter a few times in front of his sitters, and afterwards send word to his clients that unfortunately, quickly though he had worked, the subjects had moved. But this course, analogous to the plan of exposing a few empty slides in taking children sitters—which, we have more than once been credibly informed, was not an uncommon thing—is greatly to be reprehended. Far better would be some power of readily adjusting the exposure at the time of taking a snap exposure if necessary, with the power to prolong it if desirable. Most of the shutters in use have an arrangement for regulating the speed of opening and closing; but few of them have it so completely under control as to enable the photographer to alter the duration of exposure in a moment, as a changing light or a restless sitter may render it necessary.

Let us suggest an example. A photographer wishes to take a portrait of a well-bred horse, but finds when he has it before his camera that it is restless and capricious, as such animals often are. If he make two or three snap exposures he will feel sure of success of a sort; but, unless the light be exceptionally good, he may find when he developes his plate that to get a really good negative he should have given about twice or three times the exposure, or even more than that. His shutter was set to a twentieth of a second, but he had no power to alter it in an instant to a quarter or half of a second when he found his subject was still for that length of time. If he had only withdrawn his diaphragm the exposure would have been right; but then he would have had to re-focus each time the animal moved out of his place a few inches, and, besides, he could not have got into good focus all that he wished to include in the picture.

The result is that he obtains, it is true, a portrait or portraits of his subjects, but one not at all comparable with the class of work he usually likes to do; and one which, like a great many so-called instantaneous pictures, requires an explanation, when shown to anyone ignorant of photography, that it is very difficult work and cannot be expected to be equal to ordinary photographs. It must be admitted that the bulk of instantaneous photographs, though very wonderful, are very poor.

Muybridge's animals in motion, which roused the enthusiasm of the artistic world, were in the majority of cases little better than *silhouettes;* but, then, they were admired, not for their artistic excellence, but for the positive way in which they had solved a problem that had been a vexed question for centuries. They were wonderfully interesting, but, unfortunately, they were "funny" to look at; and we do not suppose that any artist has copied a single position this clever and persevering photographer obtained. His photographs will illustrate physiological works, and will always remain a monument of skill and industry; but they will never be hung on the walls of connoisseurs as works of art, as, we are proud to say, for the sake of our art, so many photographs are nowadays. They will rather be placed in the albums of collectors of curiosities, or relegated to the walls of a zoetrope or peep-show.

It is with the idea of indicating how unfortunate it would be for instantaneous photographs in general to come to such an end that we now write; but we appeal to our readers whether it is not unfortunately true that the bulk of them are worthy of no better treatment.

Whether a complete remedy exists or not is the question. With regard to it we are prepared to say that all existing shutters utilise, from the commencement to the conclusion of the exposure, a portion only of the light emitted by the object and capable of being taken up by the lens. Instantaneity is in photography only a relative expression ; but if a close approach to it characterised both the opening and the closing of the lens, leaving the portion of time required to be available for the full aperture of the lens, better value would be obtained from the lighting of the plates. This, we know, is not the case with shutters hitherto constructed; but, then, it is discovered that "the foreground gets more exposure, which is, of course, a great advantage." We say—"Let the foreground take care of itself, and let the whole subject have the maximum exposure; if necessary the foreground can easily be managed."

Many arrangements could be devised, no doubt, to meet these views, but they would possess disadvantages in practice, not the least being the risk of jarring the camera. With regard to this last important point we may say we have recently had the opportunity of examining a very simple contrivance for preventing its occurrence, and we purpose in resuming this phase of the subject next week to give a description of it for our readers' consideration.

THE DETERIORATION OF PAINTINGS AND COLOURED PHOTOGRAPHS.

The subject of the fading of photographs is one that has of late been treated upon—we had almost said, *ad nauseam;* but is the deterioration of pictures with age confined to those alone which are produced by photographic means? Can paintings themselves be considered permanent? Take, for example, water-colour drawings. Many of these, we all know, if subjected to a strong light, will, in a comparatively short period, exhibit a marked change, and more particularly if at the same time they be exposed to atmospheric influences.

It so happens that some of the pigments employed by water-colour painters, which may be unaffected by light, undergo a manifest change when exposed to noxious vapours, although if the same colours be employed in oil-paintings they would be quite permanent. This is owing to the vehicle with which they are mixed forming, as it were, a protective coating. Notably is this the case with some of the preparations of lead. We recently saw marked examples of this in some elaborately-coloured carbon pictures on opal. The artist, to soften the shadows of the face, had evidently incautiously used flake white (carbonate of lead), and upon this the atmosphere had acted, turning it to a dark metallic colour, with a lustre resembling black lead. We found upon removing this colour carefully with a sable-hair pencil that the photograph was unchanged and intact beneath. Now, white lead, when used as an oil colour, is one of the most permanent pigments that can be employed.

Oil paintings, in many respects, may be considered far more permanent than water colours, inasmuch as the pigments themselves are protected to a great extent from the action of the atmosphere by the vehicle with which they are mixed. They are also still further protected with one or more coatings of a protective varnish.

which, of course, is quite inadmissible in the case of water-colour pictures. It may be said that no artist of repute, if he knew it, would for a moment think of employing colours or other materials which in any way are liable to undergo a change. But, unfortunately, he is dependent upon the artists' colourman for his prepared canvas, his mediums, and his varnishes. We all know that even the most renowned artists' productions do occasionally, after a comparatively short time, become very much deteriorated. The colours lose their brilliancy, the white becomes degraded, and the paint cracks into innumerable fissures. Now, these changes are seldom due to the pigments themselves, but to the vehicle with which they are incorporated, or to the varnish with which the picture is coated.

The rapid deterioration of many modern paintings has now assumed so serious an aspect that the Royal Academy has, we are given to understand, taken the matter in hand; and papers are now being circulated amongst the academicians containing printed inquiries as to their methods of procedure, the vehicles or mediums and exceptional pigments they use, also the varnish employed, as well as the preparation of the ground work on the canvas, &c. These questions, if correctly and conscientiously answered, will, of course, be of immense value to artists generally, because we know quite well that when any material whatever is employed, in the production of a painting, which will not prove permanent it is done entirely through ignorance of the fact or from a want of knowledge of the character of the materials themselves.

A curious example of the rapid deterioration of an oil painting was brought under our notice a short time back. The facts are these:—Some few years ago a provincial photographer received a commission for a life-size portrait on canvas, coloured in oils. As the picture was a presentation one, and a high price paid for it, no expense was spared in executing the commission in the best possible manner. The small negative was sent to a London house, and an enlargement from it was made by the carbon process on canvas. This in turn was placed in the hands of an artist of repute to be painted. Finally, the picture was finished, delivered, and was highly commended. So far all was well; but within three years afterwards the picture was returned to the photographer cracked all over, very much like some oil paintings occasionally met with a century or two old.

The photographer, unable to account for the phenomenon, consulted the painter, who at once attributed the cracking to the carbon basis. This was by no means surprising, seeing that with all carbon prints there must always be a layer of gelatine between the groundwork on the canvas and the oil paint. Although this film, if the carbon picture be skilfully produced, will be excessively thin and very porous through the large amount of pigment it contains, yet there is the fact that the film exists. The enlargers were then appealed to, and they, at once, repudiated any responsibility in the matter, as they were sure that their work had been properly executed, and that the cracking was due to the colour or varnish employed by the artist and not to the carbon picture at all. At this point we were consulted, and, at first, were certainly inclined to suspect the carbon basis, for the reason given above; but upon close inspection, however, we noticed the cracking existed quite as much in the lights—where there could be little or no gelatine—as upon the shadows, where it was the thickest.

Now, the only way of settling the matter was by removing some of the paint to see what was the state of the carbon print and canvas beneath, and whether they were at fault. As the picture in its then present state was of no value, and another had to be done in order to save the photographer's reputation, we obtained permission to make the experiment.

Having selected a place where the cracks were the thickest and most open we commenced rubbing the varnish with the finger, after the manner pursued by picture cleaners, and soon succeeded in getting it off. The varnish being removed we next applied—first turpentine, and then benzole, to the denuded paint, and with patience finally succeeded in removing that entirely from a space of several inches, when we found the carbon print and canvas intact and perfectly free from all trace of cracks. Here was unmistakable evidence that the cracking was due to the vehicle in which the pigments were mixed, or to the varnish with which the finished picture was coated—most probably the latter; for it may be here mentioned that in removing it we noticed that it came off much easier than good mastic varnish usually does from a picture.

It is to be hoped, now that the Royal Academy has taken the deterioration of oil paintings into serious consideration, the authorities will ultimately issue a report upon the subject, which will, doubtless, be very instructive to artists generally; for it is indeed lamentable to see the way some valuable paintings, of modern production, have become deteriorated. When the report is issued, as we hope it will be without unnecessary delay, we have little doubt those who make a speciality of colouring photographs will profit by it, and so obviate cases such as that just referred to, which, we are informed—and we regret to say it—are by no means an uncommon occurrence.

THE LATE MR. C. JABEZ HUGHES.

We regret to have to announce that the publication of the portrait of our lately-deceased friend, which was promised for this number, must be deferred for another week. We have received, at the last moment, a telegram from Messrs. Sprague and Co., who are printing the portrait, giving reasons why such a delay is imperative.

From a private source we learn that Mr. Cecil V. Shadbolt has succeeded in securing a fresh series of balloon photographs. An ascent was made by himself and Mr. Dale on Wednesday, the 13th inst., from the Crystal Palace grounds, in the new balloon "Monarch," and in the course of a trip of an hour and a-half's duration several plates were exposed successfully. The voyage was brought to a successful termination at Doddinghurst, about four miles from Brentwood, Essex, at 1.17 p.m. A photograph of Blackheath is said to be a maplike one, and another, taken over the Royal Albert Dock, at a very low altitude, will, it is expected, prove "a regular gem." A new "sensation" connected with the ascent was the interesting fact that the *voyageurs* "lunched together up in the clouds!" We congratulate Messrs. Shadbolt and Dale on the results of their "aëronaut holiday."

The Convention of the Photographers' Association of America is next year to be held in Buffalo, N.Y., under the presidency of Mr. Landy, of Cincinnati. The vicinity of the Falls of Niagara will, doubtless, prove one powerful incentive for eastern (American) photographers, as well as those from other quarters, to be present at the next annual meeting.

Her Most Gracious Majesty the Queen not only sent a kind letter of condolence to Mrs. Hughes upon the death of her husband, the late Mr. C. Jabez Hughes, but also forwarded a beautiful floral wreath to be placed on his coffin when being carried to the grave.

Under the heading of "The Beautiful Snow" the *Microscope* points out the kind of organic impurities found in snow, which, added to what we recently quoted on the same subject, very conclusively shows the fallacy of the idea that melted snow forms a good substitute for distilled water. The impurities are as follow:—Living infusoria and algæ, bacilli and micrococci, mites, diatoms, and great numbers of fungi spores; also fibres of wood, mouse hairs, pieces of butterfly wings, skin of larvæ of insects, cotton fibres, pieces of grass, epidermis, pollen grains, rye and potato flour, grains of quartz, minute pieces of roofing tile, and bits of iron and coal!

We must, however, give the other side of the question a hearing In the account of the Conference on Water Supply, as published in the *Journal of the Society of Arts*, we find Dr. Odling saying—"So exceedingly difficult is it (pure water) of production, even if it ever has been produced in a pure state, that it may be regarded rather as an ideal than a real chemical substance;" and, a little further on—"Chemists speak of pure water irrespective of the fact that, for all the needs of life, the water is benefited, though to the prejudice of its chemical purity, by the presence both of its dissolved gases and of a proportion of dissolved saline matter."

We have often had the pleasure of chronicling the exploits of one or two of our contributors who, forsaking the trodden paths, have mounted in the air and used their camera, looking down upon ordinary mortals, and now, if the papers are to be believed, ballooning will become so simple an affair that we should no more think of giving an account of photography from a balloon than we should of photographing from a dog cart or the window of a railway carriage. There seems no real cause for doubting the accuracy of the account given; yet it seems to have been received with singular coolness by English journals, who might have been expected to consider a great achievement to have been performed. Neither more nor less is claimed than that the problem of aërial navigation has been solved—a question that has agitated mankind for ages. It is stated that M. Krebs, captain of infantry, ascended in a new balloon of novel shape, fitted with a director, or, in other words, a rudder; that he sailed for two miles, then, turning the rudder, retraced his path and returned in five minutes, alighting at the very door of the wooden house whence the aërial vessel started.

The subject of varnish is one of very great importance to the photographer. At present shellac is the "sheet anchor" of the photographic varnish manufacturer; but, at the same time, it may be said that other resins possess advantages that might well be made use of for the purpose. The mode of treating them, however, is not well known; hence, the few details that follow will be of advantage to those wishing to experiment:—

"Calcutta copal, and others of its class, as well as amber, which forms the basis of varnishes, are not in their crude state soluble in either oil of turpentine, benzine, petroleum, or other hydrocarbons, nor in vegetable oils. They become soluble when, by a preliminary distillation or incineration, they are deprived of 25 per cent. of their weight. This result was announced some time ago to the Academy of Sciences of France by M. Violette. The following results are from recent experiments:—1. The above resins, when heated to a temperature of 350° or 400° Cent. (about 600° to 750° Fahr.) in a closed vessel, acquire after cooling the property of dissolving in the above liquids, and constitute excellent varnishes without any loss of material.—2. When heated as above mentioned *alone*, or mixed with one or more of the liquids named, these resins dissolve perfectly in them and constitute very fine varnishes.—3. Calcutta copal, heated in this manner with one-third of its own weight of boiled linseed oil, and three-quarters of its weight of oil of turpentine, gives at once, without loss, a thick varnish, clear, limped, of a fine colour, slightly yellow, and quite fit for carriage varnish."

Some years ago a number of photographs of tree trunks, exhibited at one of the London societies, passed the ordeal of criticism unchallenged, though scarcely one of them was ticketed with the correct name, owing, if we remember rightly, not so much to the want of excellence in the pictures as of knowledge in the spectators. It has been proposed that not only tree trunks or, rather, the barks, but also their leaves, should be photographed so as to enable anyone, by comparing a disputed sample with a photograph of an admittedly-genuine one, to ascertain at once its authenticity or the reverse. The plan is certainly worth trying. A book of photographs of leaves of economic and medicinal plants would be interesting, to say the least of it.

It is, as we have said, only the other day that oxygen was produced in a liquid state, and now its density, boiling point, state of purity, &c., are matters of common information. M. S. Wroblewski, who has given so much time to the study of this subject, is in doubt whether the crystalline precipitate, when oxygen evaporates, is formed of pure crystals of oxygen, or is derived partly or entirely from possible impurities of the gas. We presume, seeing that liquid oxygen is promised as a regular article of commerce, we shall have manufacturers advertising liquid oxygen as "commercial" and "pure" qualities.

The telephone has lately been made to subserve a new purpose—the measuring of heat at a distance. As an automatic recorder of changes of temperature the new apparatus may possibly be of use in the laboratory, where every contrivance that may facilitate the regulation of temperature or the recording of its variations is naturally of value.

TOURIST CAMERAS AND LENSES.

Two articles in the issue of this Journal of August 8th particularly arrested my attention—the first a mysterious contribution by Mr. Herbert S. Starnes, and the second a complaint by Mr. W. H. Harrison about tourist cameras. I began a sort of criticism of and answer to Mr. Starnes' revolutionary doctrines, but the unusual and oppressive heat of the weather has, for a time at least, given a *quietus* to my pen on that subject. I should like, however, to give the readers of The British Journal of Photography a sort of commentary on Mr. Harrison's remarks about cameras.

As to the importance of the subject of which Mr. Harrison treats there can be no two opinions. It is a matter of the utmost concern to us that we should have apparatus light to carry and easy to bring into action. Even for those who prefer deliberation and care in their selection of views and focussing of views when selected, it is often a great object to lose no time in getting the camera ready for action at the shortest notice. Though, as a rule, I myself exercise considerable care and patience in putting my view to the best pictorial advantage on the ground glass, yet I have frequently had to hurry my selection and position on account of the time taken to erect and make ready my apparatus. During the short halt of a coach or even of a train, during the limited duration of a pleasing effect of light, and on many other occasions when time has been valuable, I have felt the force of arguments such as those of Mr. Harrison. I must say, however, that my cameras seem to be more handy than those of Mr. Harrison, who gives ten minutes as the minimum time for preparations. With my largest camera I should be inclined to put three minutes as about the average of time required for erection, screwing in lens, and opening up dark cloth; a minute may be expended in focussing, and a minute in getting a plate out of the changing-box, while, if slides are used, the last minute need hardly be counted at all.

I cannot tell what size or kind of camera Mr. Harrison uses, but the time I have guessed at suffices to "rig up" a 10 × 8 camera, by Mr. George Hare, on a stand whose lower parts turn up, when not in use, outside the upper part. The screw of the triangle is a fixture to the triangle, and by practice I can without fumbling hit off the camera hole in an instant. This possible fumbling is one of the weak points of the present system, which Mr. Harrison points out with his usual acumen. The camera travels in a knapsack canvas case, and two pulls of two straps lay the camera bare and ready to be lugged out of its waterproof nest. It is placed on the stand and screwed on closed, two brass bars are pulled, the front pushed up and clamped, and the back drawn back to a marked line in much less time than I take to write this.

But now comes the slowest, silliest, and most exasperating part of all, and delay and vexation are possible at this stage to the handiest and most experienced operator—of course I refer to the screwing of the lens into its flange. If the lens be a large one, if the screw be not a thoroughly good one, if the hands be hot or cold, but chiefly if there be any cause for haste, the lens is sure to quarrel with the flange, and the operator to "cuss" both and lose time and temper. I remember one time at the Pissevache Fall in Switzerland my hands were so benumbed with cold that for ten minutes I fumbled and stormed at the lens before it would go into its flange, so that on that occasion my waste of time amply justified Mr. Harrison's complaint. For this trouble I have now a cure that I shall at the close of these remarks bring before my readers. By the adoption of this little dodge any of my lenses can in a moment be stuck into place, and clamped there by a turn of the wrist.

Mr. Harrison seems to suggest that our cameras should be so made as to pack ready for use. I fear an ordinary camera (say 7 × 5) opened up to the approximate length required for use would be a rather bulky article to carry, and the shape would also be inconvenient. If the lens were fixed in its flange ready for action its longevity would be at stake as a useful optical instrument. But, put into my hand my present $7\frac{1}{4} \times 5\frac{1}{4}$ camera closed up as for travelling, and in three seconds I will undertake to have it rigid and ready for the stand, in three seconds after it is fixed to the stand I will have it approximately focussed, and in two seconds more I will have the lens in its place if it has not been rolled up in a cloth or closed up in a bag. I do not think Mr. Harrison could expect anything quicker than this. If I were in the habit of being in furious haste I should have a medium stop fixed in, and a shutter on, my lens, and a mark on my base-board to show the focus for that lens on an object at a given distance; by this means delay in focussing would be avoided. At present I have put matters so that the screwing of the camera to the stand is the weak point; but I have seen arrangements such that no screw was required, the camera base having plates that slid below corresponding plates on the triangle. I see nothing to prevent such a "dodge" being contrived and adopted by anyone. In my own practice very little time is occupied by the screwing operation, which Mr. Harrison's suggestions of a bayonet catch or a hollow would still further facilitate or do away with. As Mr. Harrison says—Why do not apparatus makers turn their attention to this point at once? A threaded screw is apt to be a nuisance wherever it is.

I agree "some" with Mr. Harrison about slides. They should certainly not slide, but push and catch with a spring, as he says. But I do not at all like the shutter of the slide to pull right out; that is a capital way to lose both time and plates. If the shutter be not put in absolutely square light will certainly get in; and in the attempt to put in the slide accurately time is lost, nerves are strained, and fumbling occurs. I speak from experience. The shutter should have a double hinge, and turn right back to the slide where a spring should catch it—not an elastic band, as I have seen, but a metal catch-spring. The shutter, too, should close with a spring—not a mere makeshift of a piece of bent brass, as is so common. During my Italian campaign my 8 × 5 camera had a revolving slide-shutter made of a whole lot of slips of wood glued on to leather, like things for lifting a hot kettle. This kind of shutter is, I admit, apt, but by no means certain, to let in light sometimes. Mine kept light-tight during a year of hard work.

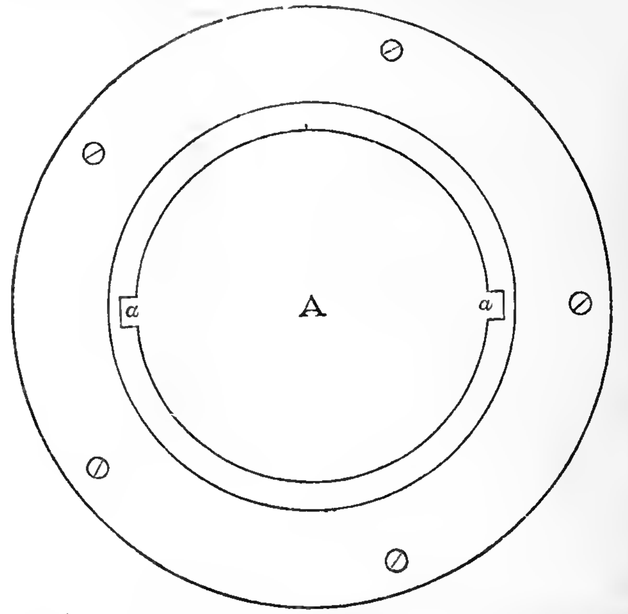
As to turning the camera on its side for vertical pictures: I much prefer to turn the back of the camera only when it can be so done, but for this action the camera requires to be square, which adds both to weight and expense. With Mr. Harrison I opine that slides might be made much lighter than they are without a sacrifice of strength; but if there is one thing that must be well and strongly made it is a dark slide, and I do not at all fancy some of the gim-crack affairs I have seen put forward as efficient slides.

A very old theme of mine is touched upon by Mr. Harrison—the weight of glass plates. So long as we have to carry dozens of these plates an incubus and a serious drawback will be felt by amateur photographers. I cannot conceive how it is that films, or pellicles, or paper with sensitive coating, have not become universal. Any-one can make films of the kind I have myself described; but it would be a burden on amateurs, and even on professional men, to make their own films, on account of the time necessary and the space required. But manufacturers ought to have less difficulty in these matters, and I am certain that films coated with good, clean emulsion would pay the makers enormously, even were they sold at a much higher price than glass. I have often thought of making a lot of films myself, leaving them on the glass, getting a manufacturer of emulsion to coat my plates, and then stripping off the films myself for carriage on my more extended tours. There are in the market films of more than one make, but my slight experience of them led me to the conclusion that the emulsion was far too slow for me, and too dirty for anyone. I hope I was unfortunate in my trial of films, but I have stated what my experience was. I do not now remember by whom the films were made. But a day will come when films will be exclusively used; and happy the manufac-turer who first turns out perfect films coated with perfect emulsion, and happy the maker of apparatus who first turns out a perfect receptacle for these films.

I have frequently noticed a great deal of time lost in changing a camera front to suit various lenses. My front has fixed to it the flange of the largest lens I use, and adapting rings enable me to put in at once any lens I possess without shifting the front. This holds good for the arrangement I mean to describe later. I am fairly satisfied with the make of my lenses for portability and safety combined; but I see no reason why the tubes should not be made of something lighter than metal, and collapsible like an opera hat. This idea will probably frighten the opticians, but I can't help it; they may rest assured I have no intention of trying to make a collapsing lens. What I do intend to suggest may give them enough matter for thought.

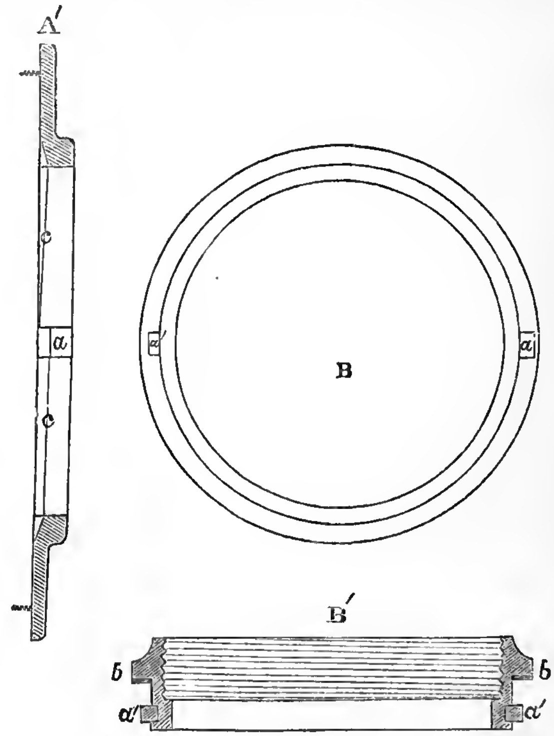
To conclude this subject: I may say that for the most part I agree with Mr. Harrison, and consider that he has done well to bring the matter of tourist cameras into public notice. I am inclined to think that he has not seen some of the cameras lately produced by our best makers. These cameras seem to me to com-bine portability and strength, lightness, and facility of use in a manner that leaves less to desire than Mr. Harrison may imagine. In all such matters we have to endeavour to strike the happy medium between lightness and strength, and such circumstances invariably leave much to the taste and judgment of the purchaser. With Mr. Harrison I urge the use of a long extension of the camera, of ample play in rise and fall of the front, of a double or circular level, of catches instead of screws, and of the insepara-bility of all parts, as well as of double-swing backs to a consi-derable extent. Slides must be light-tight first and light after.

Now for my lens idea—indeed, I do not know that the idea is mine. Mr. H. Gifford (a young engineer and an amateur photo-grapher) and I were talking over the frequent trouble of screwing a large lens into its flange, when the idea of studs slipping into a hole and then turning a little bit came up, and the lid of a gun-



A, is the flange screwed to the camera. B, the adapter into which the lens goes. A', section of A.

makers' box was instanced. After a short conversation Mr. Gifford went home, and shortly after sent me the drawing here reproduced, telling me at the same time that he had had an arrangement of the kind made for him in Edinburgh by Messrs. Kemp and Co. The arrangement may briefly be thus explained. The flange A has two sharp cut holes, *a a*, behind which are two inclined planes, *c c*, as



B' section of B.

seen in the section A'. A ring, B, fits the lens, and has two studs, *a' a'*, hard-soldered on, which slip into *a a*, the lens gets a short turn when the studs move along *c c*, an inclined plane, and clamps itself. On the section B', *b* is a leather washer, which not only helps to keep out light, but makes the clamping more secure. Nothing can be simpler or more efficient; in a moment the lens is in its place and tight, and all my lenses, with their adapters, fit B, so that it is all the same what lens I use—it is in in an instant. I have not seen Mr. Gifford's arrangement, but mine is faultless, and was made by Mr. W. Hume, of Edinburgh, to whom I can refer anyone wishing to know more of this labour-saving "dodge." When about to make a landscape photograph any means of preventing distraction and loss of temper is of great importance; it takes me all my time to think of my picture without anathematising my fingers or my lenses. ANDREW PRINGLE.

DEVELOPMENT.

THAT it is very possible for even an experienced operator to incorrectly expose a plate by 100 per cent., giving it twice the correct exposure or only half the same, will, I think, be admitted by those who work much in dry plates. For the portrait operator with his dark room at his elbow this assumption does not hold good; but for the worker in the field, with his large stock of dry plates with him, it seems to be the usual custom to carry a small developing *impedimentum* as his everyday companion, in order to be able to develope a plate or two now and then to ascertain and satisfy himself that his work has been rightly timed. This plan is certainly effective, but at the same time is a decided nuisance. When an industrious searcher after the picturesque has returned to his hotel subsequent to his long day's ramble it is quite trouble enough for him to have to change his plates and mark them. He should not need to engage in the subtleties of development, which ought, in all conscience, to be deferred to a more fitting occasion.

A plan I have had long in practice for the attainment of this end—the more effective assuring of a correct exposure—may not be without interest to many of my readers, more especially as I have not seen anything of a like nature hitherto published.

It consists, then, in using for a standard a developer which shall have a reserve power for an under-exposed plate equal to (say) 100 per cent. In case this should not be quite clear I will take an instance:—Suppose the proper exposure to be twenty seconds, and the plate has only had ten seconds. Now, by omitting one of the component restraining parts of our developer the operation yet proceeds satisfactorily, with the same result—a perfect negative. Over-exposure, on the other hand, does not present to us any grave difficulties, it being dealt with up to any reasonable limit by augmenting the restrainer. The invaluable citrate of soda of Mr. G. Watmough Webster, to which I should like to draw the attention of your readers, is here of great use to us.

I mix my developer as follows, although I do not recommend anyone to depart from a formula with which he is familiar, but rather to modify it so as to attain the same principle:—

A.

Ammonia fortis	½ ounce.
Bromide of potassium	60 grains.
Water	20 ounces.

B.

Bromide of potassium	120 grains.
Bass's pale ale and water, equal parts	20 ounces.

C.

Pyrogallol	80 grains.
Salicylic acid to saturation ......(about)	3 grains.
Water	20 ounces.

D.

Citrate of soda	1 ounce.
Ale and water	20 ounces.

The standard developer consists of half-an-ounce of A, B, and C. When we wish to fall back on our reserve of developing energy solution B is omitted in whole or in part. For over-exposure D comes into use; but it must be added very cautiously, one drachm to the above having a powerful effect. It may, however, be employed until the required action is obtained. Bitter ale I find a most valuable adjunct to the alkaline development of gelatine plates. JOHN M. CARROLL.

PHOTOGRAPHERS AND PHOTOGRAPHY IN AMERICA.

No. I.

I NOW respond to the request you made that I should furnish a few jottings of my adventures in America, so far, at anyrate, as photography is concerned.

Nothing of special photographic interest occurred on the voyage except a "shot" at the S.S. "Austral" in mid-ocean a mile off in half a gale, requiring the aid of two persons to hold the camera to the deck, the cord and elastic door-spring "dodge" being almost useless. The arrangement for stopping out the light in my cabin was somewhat novel, namely, stuffing a pillow in the port-hole, another in the electric lamp, and a portmanteau over the grating ventilator. Thus my dark room was complete. Towards the end of the voyage the weather moderated so that I was induced to try a couple of plates to show the lazy life led by passengers on board of a "Cunarder." Had the light been sufficiently good I would have taken the saloon and the smoking-room: the expressions on the gamblers' faces would have formed an interesting picture.

In New York I lost no time in visiting Mr. F. C. Beach, the President of the New York Amateur Photographic Society, who kindly showed me his newly-designed dark room; and a more complete and carefully-arranged laboratory I have seldom seen. By-the-bye, he uses professionally (as a patent agent) a large quantity of bromide paper for reproducing his drawings. These are made on the ordinary paper. The sensitised drawing-paper is placed wrong side to the front of the drawing (to avoid transposition), the whole put in a printing-frame and exposed to daylight for a couple of seconds, and developed with ferrous oxalate. By this method an inventor can have a copy of his machine by return of mail for inspection or correction, and I am informed that many copies are required, thereby bringing more "grist to the mill." Mr. Beach's dark room is about ten feet square and twelve feet high. All the waste hyposulphite of soda is poured into a square water-tight box for reduction. In answer to a question as to whether the fumes of the potassium sulphide were not obnoxious, I was told that by the method of mixing the sulphide this was entirely obviated. The sulphide is broken up into small pieces and placed in the bottom of the solution. I am rather inclined to think that the perfect ventilation of the room has a great deal to do with it, as the box or precipitating vessel is placed about midway between the floor and ceiling, and a perfect system of ventilating and heating is arranged close to the floor, thereby carrying off the fumes.

Mr. Beach has asked me to give a demonstration on making emulsion at the next meeting of the Society, which takes place on the 9th of September, and concerning this I will have something more to say in a future communication.

My next visit was to Boston. There I was cordially received by Mr. Black, well known as the "acid bath Black." He showed me many negatives he had just taken in the Yellowstone Park, or People's Park. The scenery is, I am told, beyond description, and Dame Nature has been very lavish in this quarter. The extent of the park is about 3,000 square miles; it includes several mountains, and geysers are freely distributed. I am told that the difficulties of photography are very great, especially as the hot springs set up so much steam that very clear photographic results are almost impossible; yet, upon the whole, the negatives secured by Mr. Black are wonderful. They were taken on plates specially prepared for him by Mr. Eastman, and do not bear the appearance of being very rapid. I had almost forgotten to say that the negatives are intended for lantern slides for a lecture.

After leaving Mr. Black I visited the gallery of Allen and Rowell, where, to my surprise, I saw great things. In the first place, it is seldom I have to look up to a photographer; but in this case I had literally to look upon a giant in the person of Mr. Rowell, who met me with open arms and kindly showed me all over his works, where I saw the making of dry plates, carbon tissue, &c. Mr. Rowell is happy in having the assistance of an Englishman, Mr. Derham. This latter gentleman is one of the few whom I consider a good all-round man. Mr. Rowell and I compared our emulsion experience, and in nearly every particular we agreed. This, I have no doubt, will by some of my friends be considered marvellous, as it is so seldom I run parallel with any one.

Mr. Rowell's arrangement for coating plates and his steam power for exhausting and changing the air are certainly very good. I had also the pleasure of seeing his machine for coating carbon tissue, and it struck me as being suitable for bromide paper. He kindly made some in my presence to show me that, although the thermometer in the room stood at 86° Fahr., no difficulties were experienced in setting the gelatine. The coloured carbon gelatine is placed in a trough and the paper is rapidly drawn over the surface and then over long, wide canvas bands. In a few moments it is set, and an assistant stands by cutting it off in pieces with a large pair of scissors, placing it on wooden rods to dry. I saw the tissue coated about 10 a.m., and about 2 p.m. it was nearly dry. Mr. Rowell often prepares paper in the morning, and prints, mounts, and sends out copies the same day. I mention this to show how dry the air is in Boston. Mr. Rowell has an outlet for all his surplus plates and paper, as he supplies the trade. An adieu with many good wishes from Mr. Rowell.

I "Jules Verned" to the City of Providence to visit a friend. There I found a dry-plate manufactory admitted to be somewhat disguised on account of a dissolution of partnership. Their card bears the names of J. P. Ourdan, Geo. Stillman, and J. W. Stillman. Mr. Ourdan made himself known to me as Mr. Colton, late of Burrows and Colton, of London. Judging from the size of the factory I could see no reason why a large quantity of work should not be sent out. He also had steam power employed.

From Boston I took the Fall River boat for New York, *en route* for Washington, D.C. When there I did not visit many Washingtonians, except Mr. Bell, and he seems to do good work and commands good prices. I did not learn that anyone in Washington made plates.

My next move was to Cincinnati to join the Convention (twenty-four hours' ride). On my arrival I learned that a grand *fête* was to take place at the Highland House that evening in honour of the Convention. I "made tracks" there to find some thousands of persons listening to the strains of music and the booming of fireworks. I subsequently learned that after I left many indulged in the "light, fantastic toe." Next morning I made my way to the Music Hall, accompanied by Mr. Inglis and Mr. George Croughton (old friends). The former had been up early and obtained for my wife and self the Convention "badge," showing my profession and no mistake. I was somewhat bewildered and dazed to see such a display of photographic apparatus. The Music Hall is an enormous building. I am almost afraid to venture a guess as to the numbers it will accommodate, but from the floor to the ceiling it was crammed with exhibits; and on the screens in the galleries was the exhibition of photographs, many of which were in competition for medals and money prizes given by the plate-makers for the best pictures on their respective plates. Mr. Inglis gave four medals and money prizes. Mr. Cramer also gave several. My impression, on the whole, is that, considering the short time that gelatine plates have been used in the United States, the Americans are ahead of the English. I have seen some large instantaneous studio groups which I do not think could be done in England, owing, I have no doubt, to the difference of the quality of light.

From this Exhibition I made my way to the lecture hall attached to the Hall. It is capable of seating about 2,000 persons. Here I was introduced to the President, Mr. J. H. Kent, of Rochester, N.Y., who presented me to the members. I was received with tremendous cheering. I had no idea that the few jottings and remarks I had made from time to time in England had impressed the Americans about me in such a way. I am sure that my oratorical powers have not "improved the occasion;" but I did my best, and apologised for my deficiency by stating I was no speech-maker but a photographer. I listened to an interesting paper by a gentleman (whose name I forget), and a discussion which, although suggestive, is not likely to bring forth fruit.

The following day and last of the sitting no business was done except the nomination of officers for the ensuing year, and an announcement made that the members would be photographed at three o'clock on the steps of the Music Hall.

On my proceeding to these steps a strange sight presented itself. About a dozen cameras were arranged on the opposite side of the street, their sizes varying from stereos. to 24 × 18. There was no sunshine, and the exposures varied from the fraction of a second upwards. The most noticeable was one exposed by Mr. Inglis on an 18 × 22 plate with euroscope lens, No. 8, $1\frac{3}{8}$ inch stop; diameter of lens $4\frac{1}{4}$, and 28 inches back focus; length of tube 8 inches; exposure by chronograph, half-a-second for the first two plates and six-tenths of a second for the third, three plates having been exposed. I saw one developed and it was fully exposed.

Nothing of any practical value took place at the meetings, except a demonstration of posing by Mr. L. W. Seavey, of New York, and this was evidently an advertisement for his backgrounds. I may mention that, after the nomination of officers, one gentleman on the platform rose and said he had found a good thing—that if any photographer wanted to make a gelatine negative look like a wet plate they were to add a certain amount of ammonia sulphate of iron to the hypo. bath, and allow the negative to remain in the solution until the desired end was obtained (a "mare's nest").

Great dissatisfaction all round seemed to manifest itself that so little practically was done, and expressions to the effect might be heard that they would not attend another Convention. Some good, at all events, has come out of it: the principal dealers and exhibitors have sold all their numerous exhibits.

Comparing numbers and distances travelled by photographers (many having come a thousand miles to attend the Convention), what should we English photographers have to do to draw 1,500 photographers together and from such distances. I have to thank many ladies and gentlemen for their great kindness, and for the numerous invitations I received to visit them and receive their hospitality. If I could have accepted even a tithe of them I would not have been here to tell the tale.

I am now in the "garden city" (Chicago). In my next I will have something to say about Mr. Inglis's plate factory at Rochester, as from what I hear I have reason to believe that his factory is the best organised in the United States. A. L. Henderson.

PHOTOGRAPHY IN BELGIUM.

[From Our Special Correspondent.]

Brussels, August 13, 1884.

Having arrived but a few hours ago in this city, it is not possible on the present occasion to deal with the subject of photography in Belgium; but the question may be raised whether it would not be a beneficial step to establish a Photographic Tourists' Club, open to photographers of all nations. The advantages to working photographers would be many. In the holiday season a rest on the continent would be better than one at a home seaside watering-place, because the change in life would be more thorough, the scenes to photograph more novel, the expense of the vacation less, and the opportunity would be afforded of obtaining commercial novelties of value to the profession.

For instance: here in Brussels artistic frames for photographs are commonly on sale in the shops, and in course of time they are likely to take the place of common frames altogether as the public taste improves, which taste something should be done to educate. For a painting a gilt frame is eminently inartistic. In Italy—the home of high art—artistic frames for oil paintings are coming into public use, and do as much to heighten the general features of the picture as a suitable light or appropriate surroundings in public galleries; indeed, a good frame, out of the common run, will do much to isolate the picture and to neutralise the effect of unsuitable adjacent subjects and colours. Added to this, the more cultivated patronisers of the art-science will have their attention drawn more particularly to those who take the earliest steps to elevate home art-standards.

Belgium is a good country for photographers to visit when a change on the continent is desired at the minimum of expense. Of late years the Great Eastern Railway has been most energetic in providing excellent accommodation on land and on water at very moderate charges. Antwerp is neither a fashionable place nor one in which exceptionally-high charges for the benefit of the English prevail; and English is so commonly spoken in the shops that the many who stay at home from unreasonable fear of difficulties of language will find themselves as well off as regards any information or accommodation they may require as in England. It is the same in Brussels and in the other large Belgian towns. Very little linguistic ability is necessary for foreign travel; enough French may be learnt in a week or two for the purpose. England is isolated in the general want of knowledge of the industrial part of its population in foreign languages.

At Antwerp there are many shops in which even youthful assistants speak three or four languages—Flemish, English, French, and Dutch. An English tourist is said to have made a reputation throughout Germany, and even a part of the Grisons, by travelling with the knowledge of two German words only—those for "bread" and "bed." Continental tours tend to break down home prejudices and home conceits, and to let the wanderer see how people live in free countries, where they are not generally subject to private taxation, but personally own the little portions of land on which their farms and houses are placed. One reason why, generally speaking, a smaller amount of money has a larger purchasing power abroad than in England is that the people, being in great part free from private taxation, are not forced to put a higher price upon the goods they sell. Belgium, however, is but partially more advanced than England in these matters; land is more divided in countries further south.

In the French seaside towns most accessible from England special prices for the inexperienced English are but too common, and some of them—like Calais, for instance—have nothing particularly enticing in the way of good accommodation. The railway services in France are also conducted far more in the interests of the shareholders than of the public, the trains being so arranged as to almost force those who wish to go long distances expeditiously to take first-class tickets, and no others. It is not so in Belgium, where all fares are much lower than in France or England for the same distances; added to which, if twenty persons band together to take tickets and to apply for them beforehand, they can have them at half-price. Thus it is possible to get from Antwerp far down towards the centre of Europe for a mere trifle in railway expenses. If fine scenery be desired the south-east of Belgium is mountainous and picturesque; nearer the sea it is as flat as Holland. In arranging international visits the advantages of a Photographic Tourists' Club would be felt.

Belgium is a small and prosperous country, overflowing with milk and honey. It was once the chief battle-ground of Europe. Its history teems with massacres; its very rivers ran with blood. When Spain was a rich and powerful nation it overran all this part of Europe, butchering men, women, and children in all directions in those bad old times; but now all is changed. At the same time, Belgium is now in the midst of a very serious political crisis. The clerical party having obtained an accidental majority at the last elections are making laws to put all the public schools, founded on other principles, under the authority of the priests; the feeling throughout the country is dangerously bitter in consequence. The progress of events may be watched by means of the occasional telegrams in *The Times*.

The captains of several channel boats by various routes to the continent have told me that the opening of new steamboat services and new lines of passage have not thinned down the annual number of their own passengers, but that foreign travel is becoming more general among the English. This is a healthy sign, morally and educationally good in every respect.

The Photographic Establishment of M. de Blochous.

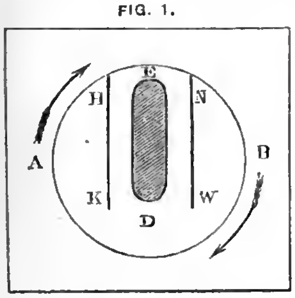
Brussels, August 20, 1884.

M. A. de Blochous, President of the Belgian Photographic Association, devotes himself chiefly to industrial and engineering photography. His works are at 73, Rue Keyerweld, Brussels, in the upper part of the city. The newest and best part of Brussels is upon the top of a hill; the older and business part of the city is upon the hill side and upon the plain below. M. de Blochous has a wide, open space of about one acre for his operations. Near its sides are his studios, photolithographic rooms, and a dwelling-house. He has been professionally connected with engineering and photography for twenty-two years, was one of the most active founders of the Belgian Photographic Association in 1874, and is now its President. Each president holds office for three years.

The *salon de reception* of M. de Blochous contains various specimens of his work. One of them is a photograph of a railway terminus at Brussels—that of the Gare du Midi—taken a little more than fifteen years ago with one of Harrison's globe lenses of 38·5 centimetres focal length, producing a circular picture 23½ inches in diameter, sharp up to the edges. This photograph is in sharp focus at all points, whatever their distance from the lens, and even in these days of advanced optical appliances M. de Blochous finds that old lens to be occasionally useful for special purposes. His photographs of oil paintings are taken chiefly with a Dallmeyer's triplet; he never retouches these in the slightest degree, but in justice to the painter gives them as they are. Among his industrial photographs is one of a tramway car built in Brussels to run in Algiers; the same Belgian company has made tramcars for Milan and other distant places, this being but one instance among many of the extended trade of Belgium with its thriving industrial population.

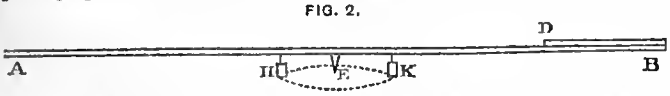
Several useful improvements in photographic apparatus have been designed by M. de Blochous, and are in constant use at his establishment. By means of one of these, each of his cameras has not only the advantages of a rising and falling front (the latter of which is so commonly absent in English cameras), but he can place the lens in any position he pleases in relation to the plate. His plan may be explained by *fig.* 1, which represents the square front of the camera carrying the circular wooden disc A B, which can be rotated either in the direction denoted by the arrows or the other way. The wooden front carrying the lens, with its flange, slides in the grooves H K and N W, whilst the orifice E D permits free motion of the lens from the centre to the circumference of the wooden turn-table. Thus his lens can be placed in any position in relation to the plate, as already stated.

FIG. 1.



In his grounds M. de Blochous has a long platform on a turn-table, used to catch the best light, whatever the position of the sun, when photographing paintings. *Fig.* 2 shows the principle. The platform B A is of skeleton framework except at D, where it is boarded to afford foothold for the operator and camera-stand. It turns upon a central pivot E, and is kept in a horizontal position by means of small wheels, two of which are represented a H K; the wheels run upon a circular iron rail denoted by the dotted lines. Removable light framework is fixed upon the end A when desired, which framework is so constructed as to hold the painting in any desired position and at any desired angle. The platform A B is about twenty-four yards long by one yard broad.

FIG. 2.



In a shed close at hand is a photographic travelling van—of more use in the days of wet collodion than at present. A portrait studio also stands in the grounds; this branch of the business is now in the hands of the successor of M. de Blochous. Among the collection of negatives in this studio are some of difficult subjects, namely, numerous specimens of jewellery upon one plate, the specimens being of the most varied kind as regards colour and materials. The lenses have rotating shutters made ten years ago by M. de Blochous; they drop in between the entrance groove in the lens mount so that no light can enter, and are worked by pulling a string.

The chief branch of business at the establishment is that of photolithography, by the process of M. Joovey, a Belgian. Heliochromy was tried for a time, but was not found to be remunerative. Joovey's photolithographic process is one of the many in which the properties of bichromate of potash are utilised, and which usually differ from each other but in small matters of detail. The plan by which large sheets of paper are evenly and completely covered is both ingenious and useful. A long V-shaped trough (*fig.* 3) is employed, with a heavy glass rod, rounded at the ends, lying free in the bottom of the trough. The paper to be coated is passed under the rod from the B side, and drawn up with the fingers from the A side, the rod rotating meanwhile by the friction. The horizontal line represents the level of the solution of bichromate of potash. This sensitising may be performed in full daylight, but the paper must be dried in the dark. The trough is lined with water-tight paper.

FIG. 3.

The base-boards—which in Belgium are called "the chariots"—of several of the cameras of M. de Blochous are on the American principle, with quick and slow motions for obtaining the focus, and the means of locking the camera when the focus is obtained. An exceedingly-useful device, especially for tourists, has been invented by M. Blochous for locking the dark slides, so that they cannot be opened in his absence by curious "young ladies" of both sexes to see what pictures he has taken. It is done by means of a little spring catch let into the woodwork of the slides—very simple, and not liable to get out of order by long usage. Directly the slide is in position in the camera the shutters pull out freely, a spring-pin in the camera pressing down the locking detent.

The plate-boxes in use by M. de Blochous are not grooved in the ordinary way, but thin slips of ebonite are let into cuts in the wood; thus the plates pack as closely as in boxes made with a double thickness of tin between the plates. The grooved slip on one side of the box is not fixed in position, but movable, so that after all the plates are in they may be fixed so as not to rattle in the box by means of a little wooden wedge then inserted between the movable slip and the true side of the box. A piece of caoutchouc tubing is placed on the top of the plates before the lid is closed; the plates, being thus steadily kept in position, are less liable to fracture in travelling.

In his developing room M. de Blochous has plenty of simple levelling-stands, every wooden shelf being utilised for the purpose. This is done merely by the use of the iron screws made from thickish wire, as represented in *fig.* 4. These are here and there screwed through the wood of the shelves; a sheet of thick plate glass may be placed on any part of any shelf on the top of three such screws, which are then adjusted until the plate is accurately level.

FIG. 4.

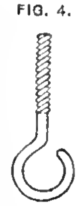


FIG. 5.

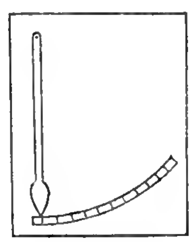

FIG. 6.

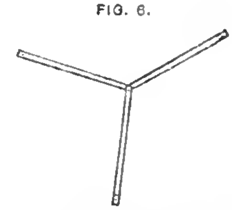

By means of another device M. de Blochous gets the base-board of his camera into a truly horizontal position on uneven ground without the use of a spirit level. The plan is represented in *fig.* 5, in which a small rectangular piece of copper carries a pendulum which points to its zero on a curved scale, when the upper part of the copper rectangle is placed against the base-board, in a direction in which the camera is level. If it point to zero in two positions at right angles to each other the camera is in a horizontal position. If it be desirable to tilt the camera its angle of elevation is indicated and can be recorded, thus introducing more precision into records of photographic operations.

A method devised by M. de Blochous for obtaining a firm footing for a camera-stand on smooth boards consists of three pieces of thin crinoline hoop joined by a central pin (see *fig.* 6). The pieces at the three ends are movable, so that the lengths of the arms can be varied; the arms also move round the central pivot. Thus the ends of the legs of the camera can be fixed in any relative positions desired, and the whole appliance for effecting this occupies small space; it is also of light weight.

The International Congress of Photographers.

The International Congress of Photographers, founded under the auspices of the Belgian Government, will not be held until May next year, when the International Exhibition will be opened at Antwerp. A preliminary programme of the work of the Conference has been drawn up, which, as yet, is necessarily private; but in a few weeks it will be submitted to the chief photographic societies of various countries

ROYAL CORNWALL POLYTECHNIC SOCIETY.

THE fifty-second Exhibition of this Society was opened on Tuesday, the 12th inst., in the Polytechnic Hall, Falmouth. Thanks to the exertions of the Secretary, Mr. E. Kitto, and of the Curator, Mr. R. N. Worth, the general arrangements were completed early in the morning, and when the public were admitted at eleven o'clock the Hall presented a neat and attractive appearance.

The Exhibition is not restricted to the Polytechnic Hall only, but a large drill hall has been engaged for the heavy mechanical exhibits, such as machinery in motion, &c., while the Polytechnic Hall is confined to the fine arts and the like, including photography. Although the Exhibition is not quite so full—especially in the mechanical department—as on some former occasions, it embraces many objects of peculiar interest. Certainly the promoters have done their best to make the Exhibition popular during the week it remains open. Lectures on scientific and other subjects were arranged for each evening, whilst for Thursday an attractive concert was announced.

There was a large and influential attendance at the opening ceremony, which took place at one o'clock. The President, the Earl of Mount Edgcumbe, presided, and there were also present on the platform the Revs. Canon Philpotts, C. W. Carlyon, W. Jago, G. Bull, F. Cole, and A. H. Malan; and Lord Renshaw, Sir John St. Aubyn, M.P., General Aylmer, Colonel Carlyon, Major Ross, Major Pender, Major Haye, Captain Bridges, R.N., Captain B. Reid, Messrs. T. B. Bolitho (High Sheriff of Cornwall), H. Liddicoat (Mayor of Falmouth), T. S. Bolitho, Jonathan Rashleigh, Barham, M.D., Jago, M.D., Howard Fox, R. Fox, W. H. Williams, R. N. Worth, F.G.S., C. Davidson, J. H. Collins, F.C.S., W. Brooks, and E. Kitto.

The Earl of Mount Edgcumbe, in opening the Exhibition, said they would forgive him if he performed that duty in the most formal manner, because he was sure they did not come to hear desultory remarks from a person who had just arrived in town, and had scarcely been able to look through the Exhibition. They came there to see an exhibition which Falmouth had made peculiarly its own, and of which that town and the county had every reason to be proud. It was an exhibition partly practical and partly artistic. One section was specially devoted to gas lighting. Gas lighting, as all knew, was introduced a century ago by Murdock, who at one time lived at Redruth, was agent in Cornwall for James Watt, and was practically the inventor of gas lighting. The first house so lighted was his own house at Redruth. Having referred to the various departments, he said the Photographic Department was quite equal to former displays, both in numbers and excellence; but no doubt they would hear more about that department from Mr. W. Brooks, who had taken so much pains to collect the exhibits.

Sir John St. Aubyn, M.P., moved a vote of thanks to the Earl of Mount Edgcumbe, which was seconded by Mr. Jonathan Rashleigh, who said it was really a privilege to have the noble Earl presiding at any gathering (applause), because he always brought wisdom, judgment, and discretion to bear on the proceedings. (Renewed applause.)

His Lordship briefly returned thanks and declared the Exhibition opened.

On the same afternoon the foundation stone of the new Observatory at Falmouth was laid by the Earl of Mount Edgcumbe, in the presence of a very large assembly. Nearly all the records are made by means of photography. The Observatory is under the management of the Polytechnic Society, and is presided over by Mr. E. Kitto, who is the chief observer, and a Fellow of the Meteorological Society. All those who attended the opening of the Exhibition in the morning were present at the laying of the stone. The total cost is estimated at £1,300. A subscription list was sent round. About £81 was promised by those present, and the ceremony closed.

The proceedings on Friday evening were rather lively, owing to the annual drawing of the Society's art-union. This art-union is established with the view of promoting the sale of professional artists' and photographers' works. The prizes are allotted in money, the winners being bound to select from such works (of professionals only) as are on exhibition; and it behoves photographers to assist in the future by taking a few shares.

At nine o'clock p.m. the drawing took place, with the following results:—

935—Mrs. Kitto	£2	0	0
1068—M. Liddicoat	3	0	0
342—Robert Fox	5	0	0
931—J. Still	2	0	0
748—Miss Steel	3	0	0
487—B. Brett, M.P.	2	0	0
1085—Rev. W. Rogers	5	0	0
954—Mrs. Harris	3	0	0
461—B. Brett, M.P.	10	0	0
991—F. Spry	5	0	0
1486—C. E. Ruse	3	0	0
1500—Miss Lake	1	0	0
96—D. J. Jenkin	1	0	0
1086—Rev. W. Rogers	1	0	0

JUDGES' REPORT.

PHOTOGRAPHIC DEPARTMENT.

THE judges have great pleasure in announcing to the Society that the exhibits in this department and its sections are fully up to the average—not only as regards numbers, but also the excellence of the exhibits generally. Of late years there has been a falling off in the professional portraiture department—that is, in the large-sized portraits. The landscapes are exceedingly fine, especially since the introduction of the rapid gelatine plates, and at the present time their manipulation is much better understood than it was a few years since. There are a few specimens of instantaneous work which possess merit that was unattainable until the introduction of the rapid plates. The amateur section is exceedingly well represented.

The judges also beg to call special attention to a series of large photographs of America, which possess great merit as photographs and are very interesting from a geological point of view. This collection has been presented to the Royal Institution of Cornwall by Mr. Richard Pearce, Jun., of Denver, U.S.A.

In the photographic appliance and magic lantern department several ingenious inventions are to be found.

PROFESSIONAL SECTION.

Mr. H. P. Robinson, of Tonbridge Wells, is amply represented by a large series of very fine studies in his well-known style. They are most admirable as gems of photographic art, and each one tells its own tale, the expression and gesture of the figures being perfect. Mr. Robinson's large picture, *The Cuckoo* (No. 695), carries off the first silver medal, the subject being a very difficult one and exceedingly well treated.

Mr. W. W. Winter, of Derby, takes also a first silver medal for a portrait study, *Sad Moments*, which, in the opinion of the judges, is simply perfect in pose and expression. He is also represented by several other charming studies, which fully illustrate the high state of perfection of the photographic art at the present day.

Mr. W. Gillard, of Gloucester, is again to the front, and has been awarded a first silver medal for his magnificent composition picture, *The Miser*, and in its favour the judges cannot speak too highly. He has also several other exhibits which are very perfect.

Mr. C. H. C. Harrison, of France, sends three frames of instantaneous studies printed in carbon, which show careful manipulation.

Mr. W. P. Marsh receives a first bronze medal for his frame No. 665, *High Seas* (instantaneous)—a series of pictures which represent in a marvellous manner heavy seas breaking over beach and esplanade.

Mr. E. C. Bowker sends a frame of cabinet pictures (No. 666), some of which are very good; but the judges think it a mistake to pose one individual so many times. The frame contains upwards of thirty pictures, and one-third of that number are of one lady.

Mr. F. Whaley sends some very good studies, the best of which is *This Little Pig Went to Market* (No. 667).

Mr. J. Milman Brown is again represented by several productions, the best of which is *Autumn Sunshine*. It is highly commended.

Mr. R. Faulkner, of London, shows a frame of very skilful studies of children in his well-known style, and also some highly-finished vignette portrait studies; but the judges regret that they are unable to award a medal (but highly commend them), owing to the high artistic finish which is put upon the photographs.

Mr. J. P. Gibson sends some clever little artistic studies, principally river scenes.—Mr. J. Tevias also contributes some excellent little studies.

Mr. A. Hendrey is represented by some studies of flowers, and also a river scene, *The First Bite*, which is very pleasing and highly commended.

Mr. John Jackson sends three frames of views, the best being No. 696, but all are of considerable merit.

A frame of interiors of *Lincoln Cathedral*, by Mr. G. Hadley, has been awarded a second silver medal, being well rendered.

Mr. P. M. Laws exhibits a frame of ceramic enamels, which are well worthy of notice.

Mr. Luke Berry sends several charming pictures, both landscape and figure. To his *Llanberis Pass* has been awarded a second silver medal, being a most charming artistic production, and full of atmosphere.

Messrs. Byrne and Co., Richmond, are represented by some very fine portrait examples printed in red carbon; but the judges notice that several of the same studies of this firm have been exhibited in former years.

Mr. G. Renwick sends two large studies of snow and frost scenes, which are interesting; and also a frame of children's portraits possessing much merit.

The award for enlargements is a second silver medal to T. J. Dixon, of London, for a *Tiger*. In the opinion of the judges it is the best enlargement they have ever seen from so small a negative. There is another one by the same exhibitor of an *Eagle*, equally good.

Mr. G. Honey has a very clever little composition picture, *Children in a Boat Feeding Swans*, but it is to be regretted that the picture is not of larger size.

AMATEUR SECTION.

The Rev. H. B. Hare has sent examples of good work of river and wood scenery.

Mr. A. Pringle's productions are very perfect and are fully up to that gentleman's former work. To his frame Nos. 805–809 has been awarded the first silver medal. The pictures are full of atmosphere, and the artistic treatment is perfection in every way.

Mr. A. Millar contributes a very careful figure study.—Mr. D. Barnett sends two frames of landscape and rustic studies. They would have been more effective if skies had been printed in.

T. H. Morton, M.D., shows two very good interiors.—A. G. Tagliaferro sends frames of interiors, &c., the best of which is frame No. 812, which has been awarded a second silver medal, the subject being well treated.

Mr. W. J. A. Grant has been awarded a first bronze medal for a frame of his well-known Polar subjects.—Mr. R. Hopkins sends three large-sized pictures printed from paper negatives, but which appear a little too heavy.

Mr. P. H. Emmerson, B.A., contributes one frame of seascapes (instantaneous), to which has been awarded a second bronze medal. The same gentleman has also sent two lifelike pictures of heads printed in red carbon, which are highly commended.

Appliances, &c.

Mr. G. Atkinson, of Chester, sends a retouching desk, which is, no doubt, effective.—Mr. F. B. Dagley sends a plate-washing cabinet, which is well adapted for the use of amateurs, and to which has been awarded a second bronze medal. The same exhibitor has also sent a plate-box so arranged that plates may be examined by the Customs without injury.

Mr. R. R. Beard, of Bermondsey, exhibits a very ingenious self-centering lantern-slide carrier, to which has been awarded a second bronze medal. He has sent also a case of so-called "safety-tubes," the workmanship of which is very good; but, as to their utility, in experienced hands their use is superfluous. The same contributor also exhibits a drawing of a screw-regulating back-pressure valve and gas tap.

PHOTOGRAPHERS' ASSOCIATION OF AMERICA.

FIFTH ANNUAL CONVENTION.

[From a Special Correspondent.]

Cincinnati, August 1, 1884.

Not having been present at any of the former conventions I am unable to speak from comparison. I am, however, told by many photographers whom I have met here that this (the fifth) is far ahead of any of the others in respect to its exhibition of photographs, both in quality and quantity, but that the actual work of the Convention was a failure. My own impression, as an Englishman, is that the work exhibited in the Music Hall during the last three days is the best I have ever seen, and the whole Convention, with one or two exceptions, was something which far surpassed my anticipations. Certainly, among the "big things" done in this great country, the annual Convention of Photographers is not one of the least.

The Convention is supposed to consist of two parts—the exhibition of the works of its members aud specimens of every kind of apparatus and accessories, either directly or remotely connected with photography, and the meeting in convention of the members for lectures, papers, and discussions upon photography and photographic matters generally.

The Music Hall—one of the largest buildings in the city of Cincinnati—was literally crowded with exhibits from all parts of the United States; while the members present—estimated variously at from eight hundred to one thousand—represented almost every State in the Union, while Her Majesty's dominion of Canada was also represented. You would think there must be some very strong inducement, indeed, to bring photographers many hundreds of miles from their homes; and, from what I could learn from mixing with the members, both in the hall and at the hotels, the main inducement for coming together was this year entirely omitted from the proceedings. The Convention itself was nothing but a squabble, continued from day to day, over amending the constitution and bye-laws and electing officers for the ensuing year. The only paper of any photographic interest that was read at any of the meetings was a very excellent communication by Mr. Ryder, and which I send you. The President's address, and one on the *Progress of Photography*, by Mr. Gentilé—who was selected at the last moment to write this paper in the place of Mr. J. T. Taylor, who was appointed last year for that duty but who was believed to have resigned since—both of which I send you.* Mr. Taylor's paper subsequently arrived, and was taken as read by a vote of the Conventiou. There was no discussion upon processes or methods of working, and dissatisfaction was very strongly expressed in all quarters.

As many of the names of exhibitors here would be unknown to your readers I purpose to confine my remarks to those things and circumstances which struck me as a stranger and an Englishman.

In the first place, then, it is one great noticeable feature that, on every hand, inducements aro offered in the way of reduced fares by rail and reduced rates of accommodation at the hotels. All the railroads (except the Pennsylvania, which would not make any reduction whatever) made the double trip at about one fare, and one of the first hotels in Cincinnati (the Palace) reduced its rates to members of the Convention to two dollars per day, which charge included bed and the usual American three meals per day.

Arrived in Cincinnati after a ride of nearly five hundred miles I made my way to the Union Hall. On entering I exchanged my annual dues (two dollars) for a white badge with gilt letters, which every member of the Convention wore upon his breast, and which was his passport to the interior of the building. Passing through with this badge I found myself in a perfect maze of photographic backgrounds upon frames stuck up in every imaginable way, and forming alleys through which I had to pass to get to the floor of the hall, but which seemed designed to lead the unwary away from the door and cause him to lose himself among backgrounds and accessories, such as balustrades, cottage porches, &c., &c.

While trying to pass through this maze I came upon what the attendants told me was the most successful accessory ever made for children. This was a very wonderful profile of a pony with a saddle on. It certainly was "most fearfully and wonderfully made;" for, while one of the attendants was screwing his head in various positions, the other was putting his legs in the several attitudes of galloping, trotting, and walking, and I should be puzzled to tell you which was the most unnatural.

Having escaped from this thing I found myself at the door of the hall—certainly the largest building of the kind I have ever seen—and paused to take in a general view. It had the appearance of a fair. All over the floor were stands and booth-like places, occupied by the various stock dealers. Some were exhibiting great pyramids of dry plates from 20 × 24 to quarter size, cameras, lenses, camera-stands, and, in fact, everything wanted (and somethings not wanted) in a photographic business.

To the right of the centre door Mr. L. W. Seavey had his stand for exhibiting his backgrounds, accessories, &c. One of the principal novelties of his exhibit was backgrounds and accessories (exterior) in colours. The landscape and the set pieces—consisting of tree stumps, rocks, &c.—were coloured after nature. Mr. Seavey was giving a lesson to a large crowd in the art of posing, using a trained female model before his background, illustrating the use of his accessories, &c., &c., with apparently great success.

Passing down the centre of the hall, where was the stand of the well-known Scovill Manufacturing Company, we come to another familiar name—Anthony and Co. Both these houses are known in England as very large stock houses, and both were here represented by very large exhibits in apparatus of all kinds. Mr. T. H. McCollin, of Philadelphia, exhibited some splendid platinum enlargements, and others in the gallery by Hoyt and Siebert, New York—these last-named exhibiting, also, prints on fabrics of great brilliancy and pleasing tone. I shall have more to say about these platinum prints further on, so passing these libels on a process which, in my opinion, is to be the process of the future for enlarging, I reach the platform.

Here, on the right, is the stand of the St. Louis photographers, presided over by Mrs. Fitzgibbons, who had a pleasant smile and hearty greeting for all. Behind the stand were two large barrels, which were kept filled with lemonade—Mrs. Fitzgibbons' contribution to the refreshment of the members of the Convention. On the other side was a stand surmounted by a gigantic "eye." This was the stand of that named newspaper, which is now a photographic publication—not, as formerly, a newspaper with a photographic section attached to it. The *Eye* is, I think, the only weekly journal devoted to photography in America; and this has to be filled up with stories, extracts, &c., which are not photographic. Mr. Gentilé is, I believe, both proprietor and editor.

At the back of the platform is a large collection of pictures, the work of Mr. McEntee with the air brush, the largest of which is an immense head of the President of the Convention, Mr. Kent, of Rochester, N.Y.; but it is not by any means a flattering portrait of that gentleman. Mr. McEntee is here surrounded by a crowd of photographers who are watching the growth of various portions of the human face by means of the air brush, manipulated by that clever gentleman. The air brush has quite a brisk sale; but I followed in thought the purchaser to his home, and imagined his disappointment when he found that the *man* had a great deal more to do with the result than the *brush*. I must do Mr. McEntee justice and say that he does not claim anything for the air brush, but that it is a tool which, in educated hands, will produce effects of high finish upon a photograph with a great saving of labour. It is, undoubtedly, an ingenious invention, and in capable hands produces a certain class of effect in a marvellously-short space of time.

Leaving the platform and passing into the corridors on each side of the main hall I am again among backgrounds, interiors, exteriors, and combinations, the quantity of which is enormous, and the quality above the average of English background painting. The exteriors have more ornament about them than we like in England; but as American rooms are more ornamental than the average of English apartments it is accounted for. Mr. Ashe, of New York, has here a fine exhibit of backgrounds of more than average quality. But in all the backgrounds—not excluding Mr. Seavey's—there is too much of the picture and too little of the background; that is, the artist pays more attention to making the background look pleasing in itself to the eye of the purchaser than to the fact that it is to be used simply as a support to, and accessory of, the portrait. Leaving the backgrounds I pass up the stairs to the upper floor, where are more backgrounds and some screens, with the competition pictures for the Inglis prize. Mr. Inglis is one of the dry-plate makers who has offered large prizes for the best collection of portraits and views upon his plates. And a very good collection is here exhibited, indicating as much the skill of the manipulators as the quality of the plates. Mr. Elton, of Palmyra, N.Y., appears to have taken both first and

* We regret to say that the President's address and Mr. Ryder's communication have failed to reach us up to the moment of our going to press.—Eds.

second prizes; at anyrate, he has two prizes—one for the best general collection, and the other for portraits on 14 × 17 plates. They are all very fine, the last-named demonstrating, both by position and expression, that the exposure was very rapid. Passing this collection I find a number of exhibits of various qualities, all being good average work, with here and there some fine instantaneous work—street views and yachts.

But this gallery is only the approach to the Exhibition proper, which is reached by crossing a kind of bridge that is over the place on the ground floor where the dark rooms of the various dry-plate makers are situated. Passing over this bridge I find myself in the largest and most important portion of the exhibition of photographs, a description of which I must reserve for my next communication.

EDWARDS'S MACHINE FOR COATING PLATES.

THE complete specification of Mr. B. J. EDWARDS's Apparatus for Coating Photographic Plates or Paper with Gelatine Emulsion is now published, and is as follows:—

MY invention relates to an improved method of, and apparatus for rapidly applying an even layer or coating of gelatine emulsion to sheets of glass, metal, paper, or other surfaces for photographic purposes.

In carrying out my invention I make use of a trough or vessel containing the emulsion, and also of a metal roller working in bearings and made to revolve in the trough which contains the emulsion with which the plates are to be coated.

The length of the roller and trough must be slightly greater than the width of the largest plate to be coated, and I fix the said roller and trough above and across a travelling band or table, which carries a continuous train of plates to be coated.

In order to carry out my improved method of applying an even coating of emulsion to the surface of the plates, I make a scraper—preferably of sheet metal or ebonite—of suitable length and thickness, and I fix this scraper parallel to the roller so as to turn on pins or centres at or near the lower edge, and, by means of a lever, weight, or springs, the upper edge of the scraper is made to press against the roller, which revolves in the trough; and I make the scraper of a convenient shape and width, and fix it at any suitable angle, so that the lower edge rests upon, or nearly in contact with, the surface of the plates or paper to be coated.

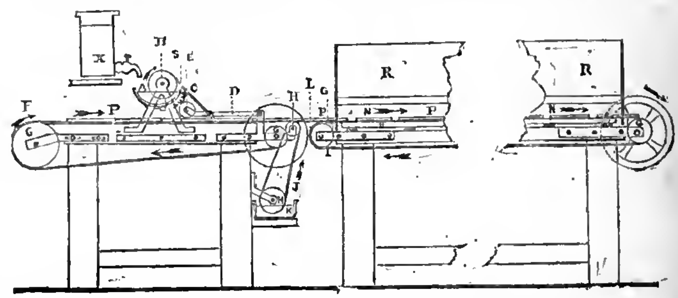
When the roller is made to revolve in the emulsion, the solution which adheres to the surface of the roller is taken off by the upper edge of the scraper towards which the roller revolves. The emulsion then flows down the scraper to the surface of the plates, which are carried by the travelling band below. By this means the plates are coated with an even layer of emulsion, the thickness of the coating being regulated by the relative speeds of the roller and the travelling band which carries the plates. In order to coat plates of various sizes I make the above-described scraper removable, and when required I replace it by another similar scraper of the length required to correspond with the width of the plates to be coated. In order to admit of coating plates of different degrees of thickness I make the centres or pins at the lower edge of the scraper to work in bearings fixed to a movable frame or pair of side rods, pivoted or hinged at one end, and carrying at the other end a roller or guide, which rests upon the surface of the plates as they pass beneath the scraper. By this means the frame or rods carrying the scraper rises and falls in proportion to the thickness of the plates, which are thus allowed to pass under the scraper without obstruction. Sometimes I attach the scraper to the side of the trough, and support the trough itself with the scraper attached by means of pivots or bearings upon the movable frame or side rods before described. In order to facilitate the cooling or setting of the emulsion after it has been spread upon the surface of the plates, I cause the travelling band carrying the plates to pass over a table or slab artificially cooled by being kept partly immersed in ice water or other cooling substance contained in a metal tray within which the slab rests, and I cover the table or slab with a metal tank containing ice or other cooling substance. The tank is supported so that the under side is only a short distance above the slab, thus forming of the space between the slab and the under side of the tank or cover a cooling chamber or tunnel through which the plates pass. The cover or tank also serves to protect the plates from light and dust after they have been coated with emulsion. By the above-described means the emulsion is rapidly set, and the plates are very quickly ready to be removed from the travelling band and placed in racks to dry.

In practice I prefer to make the travelling band in two separate portions of unequal length; that is, I make two endless bands to travel in the same direction. One of these bands, which I call the "coating band," is used only to carry the plates under the trough and scraper. The plates then pass on to the other band, which I call the "setting band," and which carries the plates over the cold slab and through the cooling chamber before described. Each of the above-mentioned bands works over a pair of rollers or drums, fitted at one end with a driving pulley, by means of which the band is made to travel in the required direction, the setting or cooling band being made to travel at a slightly greater speed than the coating band in order to cause the plates to separate from each other as they pass into the cooling chamber.

For the purpose of cleaning the back or under surface of the plates, and removing any emulsion which may have been spilled on to the coating band, I make another endless band of rubber cloth passing over a pair of rollers of suitable diameter, and I fix one of these rollers so that the cleaning band just touches the coating band and the under side of the plates after they are coated, and I arrange the other roller, which is driven by a pulley, so that it revolves in and carries the endless band through a trough of warm water. By this means the back or under surface of the plates is cleaned, and the travelling bands, which carry the plates, are kept free from emulsion.

For coating paper with gelatine emulsion for photographic purposes I use my improved machinery and apparatus, substantially as above described and in a similar manner, with the exception that I dispense with the cleaning band and one of the rollers, and I use the other roller and the trough for the purpose of wetting or damping the paper previous to its being coated; and I use another roller or squeegee for the purpose of removing the excess of moisture and causing the paper to adhere to the coating band before being passed under the trough and scraper. The paper when coated passes through the cooling chamber, after which it is cut into convenient lengths and hung up to dry. In this manner a continuous length of paper can be uniformly coated with a layer of gelatine emulsion of any desired thickness. In using my improved machine for coating plates or paper I actuate the rollers and bands by means of pulleys of suitable diameters to give the speed required, and driven by a gas engine or other suitable motor.

The endless bands may be made of india-rubber cloth or other suitable flexible material; but I prefer to make the band which passes through the cooling chamber of woven wire or thin metal plate, in order to cool or set the emulsion as rapidly as possible. Sometimes, instead of ice, as above de-



scribed, I use a current of cold air or vapour for the purpose of setting the emulsion on the plates or paper in the cooling chamber. In any case this chamber or tunnel must be of sufficient length to allow of the film of emulsion being perfectly set or stiffened before the removal of the plates or paper from the band. The length required will depend greatly upon the speed at which the machinery is driven. With a moderate speed I find fifteen feet a convenient length for the refrigerating chamber or tunnel. By means of my improved machinery and appliances as above described, photographic plates or paper may be prepared or coated with gelatine or other sensitive emulsion with greater rapidity, certainty, and uniformity than has hitherto been practicable by any other method.

The accompanying drawings show the various parts of my improved machinery as described in the above specification. I do not, however, confine myself to the precise details of construction as shown or described, as the same may be somewhat modified without departing from the principle of my invention.

A is the trough containing the emulsion. B is the roller. C is the movable and adjustable scraper. D is the pivoted frame which carries the scraper and sometimes the trough. E is the grinding roller. F F is the travelling band for coating. G G G are rollers carrying the travelling bands. H H are similar rollers to carry the endless band for cleaning the plates. J is the cleaning band. K is the trough containing water for cleaning or washing the band. L L is the travelling band carrying the plates through the cooling chamber. M is the cooling chamber or tunnel, closed at the sides and open at each end. N is the cold slab over which the travelling band passes. O is the metal tray in which the slab rests. P P are the plates, before and after being coated. R is the metal tank or cover over the cooling chamber. S is the spring which presses the scraper against the roller. X is a reservoir of emulsion for replenishing the trough.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I wish it to be understood that I do not claim any novelty in the use of a roller revolving in a trough of emulsion as hitherto used for applying a coating of emulsion to photographic plates and for other purposes, nor do I claim the use of an endless band for carrying the plates, as described in Swan's specification, A.D. 1879, No. 4,607; but I claim as my invention:—

Firstly. The movable and adjustable scraper or scrapers of any suitable shape or size, in combination with the roller and trough, for the purpose of applying the coating of gelatine or other emulsion to the upper surface of the plates, as described.

Secondly. The cooling chamber, or artificially-cooled table or slab, in combination with the endless band carrying the plates, in order to facilitate the setting or cooling of the gelatine emulsion after it has been applied to the surface of the plates or paper by means of the roller and scraper, or by any other method.

Thirdly. I claim the endless band, as above described, for cleaning the back or under surface of the plates after they have been coated. I also claim the arrangement of the pivoted frame or rods which carry or support the scraper, and sometimes the trough, together with the roller or guide, in order to allow of the use of plates of various degrees of thickness.

Our Editorial Table.

PHOTOGRAPHY FOR AMATEURS. By T. C. KEPWORTH.
London: CASSELL & Co. (Limited).

UNLIKE another *brochure* for amateurs which we had occasion to notice a few weeks ago, this bears internal evidence of having been written by one who is quite competent for the duty. Being non-technical, the language employed is such as to be understood by every reader, and, "taken for all in all," it is a manual that can be well recommended for tyros.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AT the meeting of this Society, held on Thursday, the 14th inst., the chair was occupied by Mr. S. C. Salmon.

Mr. J. B. B. WELLINGTON said that it had recently been recommended to use gallic acid in the development of gelatino-bromide plates. He had experimented with it by making up an ordinary developer, then developed one plate with that, and another with the same to which had been added gallic acid in the proportion of one grain to the ounce. He found that the addition somewhat slowed the development, and caused greatly additional exposure to be required—something like ten times that necessary with the normal developer. He produced plates illustrating the facts to which he had spoken.

Mr. W. COLES inquired whether Mr. Wellington had made comparative experiments with citrate of potassium against gallic acid, which appeared to have a very similar influence.

Mr. WELLINGTON had not made direct competitive trials, but the action appeared to him to be about the same.

Mr. A. HADDON showed some prints from negatives of shipping scenes. The plates had been exposed for an equal length of time; but the first one developed showed over-exposure and weakness, while the second had been restrained in development with a small quantity of gallic acid, and the result was quite satisfactory. In answer to questions, he (Mr. Haddon) continued that he had not made direct comparative experiments with gallic acid against citrate of potash, and that the plate developed with gallic acid had taken longer to develope than the other.

Mr. WELLINGTON thought that with gallic acid the deposited silver was browner in colour than without it.

A question was asked whether difficulty had been experienced during the recent hot weather in the manipulation of gelatine plates.

Mr. W. M. ASHMAN mentioned the case of a photographer known to him who had found his films one hot day dissolve away in the developer, and this without frilling. All the other plates exposed that day were saved by being kept till the evening, and then employing ice. He had also found recently that films when being varnished were apt to run at the corner where the varnish was poured off. Various suggestions were made, pointing to the accumulation of water in the varnish; but he considered that this was not the true explanation, as there could not be water enough to make the difference.

Mr. E. H. DERHAM, of Boston, U.S.A., was introduced to the meeting, and showed examples of the work of the establishment with which he is connected. These consisted of cabinet photographs of remarkable clearness and brilliancy of tone. In answer to inquiries, he (Mr. Derham) said that the prints were from negatives produced on plates of what was considered rather a slow make for gelatine. They had been prepared by precipitating the silver bromide in the presence of a small quantity of gelatine, and then, after washing, emulsifying for about two hours in the full quantity of gelatine, to which had been added a little ammonia and bromide of potassium.

Mr. W. E. DEBENHAM remarked that that was the Abney process with Stebbing's modifications. In his own experience he had been able to get good, slow plates with the Abney process; but he found that continued stewing, or, indeed, any treatment which he had tried that was expected to confer great rapidity, did not do so, but induced fog.

Mr. DERHAM said that he agreed with Mr. Debenham that fog supervened if rapidity were tried for. In answer to inquiries as to the method of printing he adopted, he said that he used, as was customary in America, ammoniacal fuming and toned with the borax bath. The prints were well washed and salted before toning, and after fixing the hypo. was washed out in about ten minutes by a rotary spray washing machine.

Mr. DEBENHAM then said that he had a suggestion to make. They had seen displays of transparencies for the lantern produced by different methods; but as the negatives employed had been different any exact comparison of the processes used was difficult or impossible. He proposed that (say) three negatives should be selected—one portrait, one view, and one architectural—and that these should be printed from in various processes. Perhaps Mr. Cowan would print in gelatino-chloride by development, Mr. Ashman in citro-chloride, Mr. Wellington in gelatino-bromide, Mr. Henderson or Mr. Ayres in wet collodion, and any other members who would be willing to print examples by other methods should be invited to do so. If no one else volunteered, he (Mr. Debenham) would make carbon transparencies. He proposed that the production of these transparencies should be considered not in any sense as a competition between the members, but for comparison of the results of the various processes; and he suggested that by each method prints should be made of different depths—one such as would be considered suitable for reproduction and enlargement, and at least two of slightly-different depth suitable for lantern display. This would probably allow of a set being shown in the lantern of about the same depth from each process.

The proposal was approved by the members, and it was understood that it would be carried out.

MANCHESTER PHOTOGRAPHIC SOCIETY.

ON Wednesday, the 13th inst., the members of the above Society, in accordance with the previously-arranged programme for summer trips, paid a visit to Kirkstall Abbey, near Leeds.

The morning of the day opened somewhat threateningly, and it was feared by several of the party, on assembling at the railway station, that the object of the excursion was in danger of being defeated by the setting in of rain. Happily, however, as time wore on the clouds began to disperse, and when the train arrived at its destination everything wore as attractive an aspect as the brightest summer sunshine can ever make a smoky, manufacturing district appear.

Kirkstall Abbey is situated on the banks of the river Aire, about three and a-half miles north-west of the busy town of Leeds, and can be reached from the Wellington Station by the tram cars, which run to and fro about every ten minutes. The Abbey was founded by Henry de Laci in 1152, Alexander, prior of Fountains, being the first abbot. At the dissolution of the monasteries in 1540 it passed into the hands of Cranmer, archbishop of Canterbury, and ultimately came into the possession of the Earl of Cardigan.

In 1856 a committee of local gentlemen, with the laudable object of preserving so interesting a ruin, as much as possible, from further depredation and decay, took the ground and building on lease, throwing it open to the public on payment of a small admission fee to cover the expenses of a caretaker and such necessary repairs as might from time to time be required.

The situation of the Abbey at the time of its foundation, in what would then be a charming pastoral valley through which meandered the crystal waters of the Aire, could not have been more wisely chosen, and it requires no great stretch of imagination to picture in one's mind the tranquility of such a scene in which no more discordant sounds were ever heard than the bleating of flocks and the lowing of herds, combined with the music of the vesper bell.

Although the surroundings of this once-sequestered spot have so greatly, and so sadly, changed, there is still plenty of food for the camera, and notwithstanding the smoke and bustle of the surrounding manufactories and ironworks, and the pollution of the river until its waters have acquired the intensity of printers' ink, there is probably no ruin in the United Kingdom where "lines of beauty" in composition can so readily be obtained from so many different points of view. The style of architecture is of the chastest Norman; and, when seen under such favourable conditions of light as were vouchsafed to the Manchester members on the 13th, cannot fail to satisfy the most fastidious view hunter.

After spending a considerable portion of the day at the Abbey, and exposing a large number of plates, the party drove to Adel Church—a distance of about six miles. As none of the gentlemen had ever previously visited the place the ground was quite new, and the drive was consequently greatly enjoyed; but on alighting at the gates a general feeling of disappointment was expressed at the first sight of the church, on account of its apparently severe plainness. A closer inspection, however, soon revealed the presence of various architectural enrichments of great antiquity and interest; and, as time was getting on, cameras were quickly set to work. Much of the church is very ancient, having been erected in 1140, and, like Kirkstall Abbey, the style of architecture is Norman. In the interior is a very fine chancel arch, of which, had time permitted, it would have been a great pleasure to many to have obtained negatives. The south doorway is very imposing, and an unique corbel runs round the upper part of the exterior walls; but the south wall has been somewhat marred by the introduction of two modern three-light windows quite out of keeping with the rest of the architecture. Some good negatives were obtained of general views as well as of details.

Tea having been ordered at the "Star and Garter," Kirkstall, the return drive was commenced about five o'clock. On passing through Headingly, "Jehu" pointed out the famous oak of that place, and also its "faithful representation" as limned on the sign of the village inn hard by, which establishment has adopted the oak as its patron saint.

On arrival at the hotel Mr. McKellen volunteered to occupy the interval during the preparation of tea by taking a group of the party with his newly-invented, and admirably complete, camera, the size being 12 × 10. Careful note being made of the time consumed in unpacking and opening out, it was found that the unstrapping of the stand, taking the camera out of the case, and fixing all up ready for focussing, occupied but one minute, and that without the least hurry.

The party returned to Leeds in time for the 7.20 train to Manchester, and on the way unanimous expressions were made of the great satisfaction and pleasure which had been derived from the day's excursion and work, and not a few encomiums were passed on "mine host" of the "Star and Garter," who had catered with so much courtesy and reasonableness.

On Saturday afternoon last, the 16th instant, another trip of the above Society was made to Middlewood—a charming sylvan clough lying to the right of Buxton-road, between Hazel Grove and Disley. The place being easy of access from Manchester, and also having two railway stations, has long been a favourite resort for the neighbouring townspeople. The valley, through which runs a footpath for about a mile in length, abounds in choice "bits" of wood and water, and is admirably suited for small plates or stereoscopic pictures. A few open spaces afford opportunities for taking large pictures; but generally the trees are too crowded for sizes much larger than half-plate. On the occasion referred to, under the able leadership of Mr. Coote, a considerable number of plates were exposed, the light being of the very best, and the foliage at occasional periods being perfectly still.

On Saturday next, the 23rd instant, Messrs. Chilton and Pearson will lead another excursion to the Bollin Valley. As it is thought desirable in this case to make a slight departure from the programme as to the time of starting, members will please note that the train leaving the Central Station at 12.43 for Peel Causeway is the one by which the party will travel. It is further desirable to call attention to a special excursion which has been arranged to Ashbourne, for Saturday, the 30th inst. The train will leave London-road Station, L. and N. W., at 9.20 a.m. Excursion tickets—3s. to return on the same day, and 4s. 6d. to return on the following Monday—can be obtained at the station on the morning of departure. The members of the Derby Photographic Society will join the Manchester members at Dovedale.

ST. HELENS ASSOCIATION FOR THE PURSUIT OF SCIENCE, LITERATURE, AND ART.

PHOTOGRAPHIC SECTION.

THE annual meeting of this Section was held at the Association Rooms, on Wednesday, the 9th ult., Mr. Heather occupying the chair.

The minutes of the previous meeting having been read and confirmed, the Hon. Secretary read the

ANNUAL REPORT.

The Photographic Section entered upon the second year of its existence this month. Eight new members have been added to the list since its formation, whilst, on the other hand, four have resigned. Up to the present we have entirely relied upon Mr. Heather for demonstrations, of which he has brought before you the following:—*Enlarging on Gelatino-Bromide Paper* (twice), *Preparation of Gelatino-Bromide Emulsion*, *Preparation of Lantern Slides*, and *Reduction of Negatives*. One evening was devoted to photography by artificial light and was fairly successful. The Section took part in contributing to the interest of the proceedings of the *conversazione* on January 24th, 1884. A large collection of photographs were shown, and Messrs. Heather, Morton, Taylor, and J. F. Houghton were busily engaged in photographing the visitors by the collodion method on ferrotype plates. One outdoor meeting has been held at Knowsley, which was very well attended. Besides the above a number of interesting exhibits of apparatus, lantern slides, prints, &c., have from time to time been laid before you.

The Hon. Treasurer's statement was then laid before the meeting, and showed a balance of £1 13s. 10d. in favour of the Section.

Mr. SHERLOCK moved, and Mr. BROOK seconded, that the annual report and balance sheet, as now submitted, be adopted. This was carried unanimously.

The following officers were elected for the coming year:—*President:* Mr. Heather.—*Hon. Treasurer:* Mr. Crooks.—*Secretary:* J. F. Houghton. —*Auditors:* Messrs. Bewley and Loader.—*Committee:* Messrs. Brook, Morton, Sherlock, J. Houghton, Taylor, and Bewley.

It was resolved that a 15 × 12 burnisher be purchased for the use of members.

Mr. TAYLOR said that a few days ago he was making a transparency, and, believing the emulsion to be a slow one, gave a lengthened exposure. When taken out of the frame in the dark room he was astonishsd to find a positive picture on the plate. He fixed at once and got a negative—a negative from a negative.

Mr. Brook exhibited a number of very fine views taken near Leek, North Staffordshire, and the Chairman showed a number taken at Winwick.

The meeting was shortly afterwards adjourned.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The next monthly technical meeting of this Society will take place on Tuesday next, the 26th instant, at the Gallery, 5A, Pall Mall East. The chair will be taken at 8 p.m.

Correspondence.

THE SODA DEVELOPER.

To the EDITORS.

GENTLEMEN,—Kindly allow me to reply, under the above heading, to Mr. Charles Stephens' very pertinent question in your last issue. Finding that he gets frilling on two different brands of plates with the soda developer, he wishes to know how to prevent the said frilling.

Well, to be candid, with the individual plates he uses I do not know. This much, however, I can say—that the professional photographer alluded to in my article of the 1st inst. uses a cheap commercial plate, which many will identify at once when I say that this plate has no substratum but a line all round the plate of some solution that holds the film firmly, and this plate does not frill with the soda. Yet, in the unusual heat we have had of late, he told me he saw some slight indications of frilling, upon which I advised him to use alum solution plentifully, both before and after development. Another thing, too, in the very height of summer: the developer proper may be diluted with double the quantity of water without any ill effects whatever, while the frilling tendencies will then be much reduced. The washing of the negative, also, was best effected with very cold water, to minimise all risks.

Regarding my own plates: I found it necessary to use ten drops per ounce of emulsion of chrome alum solution—strength: alum three grains, water one ounce. Now, only yesterday (14th inst.) I exposed and developed one of my own plates with the soda developer before a gentleman from Bristol, who, having business in Gloucester, pushed further to Cheltenham purposely to see me about the treatment of the plate after my own fashion. The plate behaved admirably well, and I should not be surprised to hear that this gentleman had adopted this system of development altogether.

Why I did not name the individual commercial plate which I know to stand soda is because I am aware it is not usual in the Journal; but I shall with pleasure send the name of the firm and plate to anyone on applying to me enclosing a directed and stamped envelope.—I am, yours &c.,

22, *Priory-street, Cheltenham, August* 15, 1884. A. F. GENLAIN.

To the EDITORS.

GENTLEMEN,—My experience with this developer has been somewhat similar to that of your correspondent Mr. C. Stephens. There is no doubt that the quality of the negative produced by the soda developer is very fine. Up to the present week the frilling noticed was almost imperceptible, and in no single instance did it encroach on the picture. This week, however, with the same make of plate—which never by any chance frills with the ammonia developer—I have been unable to obtain a single negative, the frilling being something desperate.

There is not the slightest doubt in my mind that the high temperature we have been having here lately has had to do with it. On finding my first plate going this way I tested the temperature of my solutions, and found them standing about 70° Fahr., while the water from the tap showed a constant temperature of 60° Fahr.

It is very unfortunate that at a somewhat high temperature the soda developer should act in this way, for it is capable of giving very fine results. With the ammonia developer and with the solutions and water at the temperatures above mentioned not the slightest indication of frilling manifested itself.—I am, yours, &c., WILLIAM LANG, JUN.

Cross Park, Partick, August 16, 1884.

NETLEY ABBEY.

To the EDITORS.

GENTLEMEN,—Kindly inform my brother amateurs, through the Journal, that should they have a wish to take a "shot" at Netley Abbey permission must first be obtained. This, I am told, can be done by applying to T. Chamberlayne, Esq., Cranbury Park, Winchester.

For want of the above knowledge I was greatly disappointed and annoyed when refused admission on the 5th inst., as I had been told in Southampton no permission was required.—I am, yours, &c.,

24, *Maxwell-road, Fulham, S.W., August* 16, 1884. P. J. KING.

EMPLOYERS AND ASSISTANTS.

To the EDITORS.

GENTLEMEN,—I beg to be allowed, with your kind permission, to draw the attention of the public (photographic) to a grievance touching sorely assistants in general, and that is the deception practised by some employers when engaging their assistants.

One will often see an advertisement of the following description:—"Wanted an operator and retoucher of first-class ability. State terms, &c., &c., &c." Now this is, of course, answered by one seeking such an appointment, and, everything being satisfactory to the employer, he is engaged. Upon his arrival the assistant is put to work fitting up show-cases with specimens of his skill; but as soon as this is accomplished he is cooly told by his employer that he will have, in addition to his legitimate duties, to perform others, such as "burnishing," "toning," "sweeping-up," "dusting," "rearranging negatives," "cleaning glass," "sensitising," and work from 8 a.m. until 9 or 10 p.m. He is bound, of course, to put up with these indignities for the nonce, as not being a millionaire he has generally to wait until a more suitable position turns up.

If an employer wants the services of an all-round hand, why does he not state it in his advertisement, and not entrap a good man into a position he would never have accepted had he known the true facts of the case?

Against such deceptions I would warn all who are seeking employment in the future, for I feel I am not the only one who has been entrapped into such servitude.

I would also respectfully draw the attention of all those photographers who resort to such nefarious practices to the fact that the assistant is in most cases equal, and in some superior, to his employer in photographic knowledge.

I beg the assistance of all right-minded men to the putting down of such scandalous proceedings. I love my profession, and would like to see it rise above all such petty meannesses.

In conclusion: I would suggest the formation of a club composed of none but first-class assistants, out of which employers could be furnished with the best material and to pay a yearly fee.

Apologising for trespassing upon your time and space,—I am, yours, &c.,
ASSISTANT.

MR. GENLAIN'S DEVELOPER.

To the EDITORS.

GENTLEMEN,—If Mr. Charles Stephens will put a good lump of rock alum in his washing cistern, and mix a little with his developer, he will have no frilling. The colour of the plate will be a rich, tawny-yellowish brown, similar to the double sulphate and ammonia developer by the wet process, and the resulting prints will be very soft and harmonious.

This is my experience with Rouch's plates, which are somewhat analogous to Mr. A. F. Genlain's own make. Amateurs and professionals can procure these as easily as I do. Epsom salts will also prevent frilling.—I am, yours, &c., W. HARDING WARNER.

P.S.—The water in the cistern will possibly come out a delicate cobalt blue on the addition of the alum.—W. H. W.

THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN: ITS REPORTS AND THE PHOTOGRAPHIC PRESS.

To the EDITORS.

GENTLEMEN,—The nature of Mr. W. E. Debenham's letter (August 1st) in reply to my last letter on this subject demands that I should not let it pass without notice. I now gather that Mr. Debenham intended to impress upon me that "misrepresentation" is a "serious charge" if brought against *himself*, who had not misrepresented me.

Now, when writing my last letter I had not so understood his words—partly owing to this fact: that I had never intended to include him among "the other writers," and, still more, owing to the form of his sentence, I concluded that he meant that to use the word "misrepresent" as characterising the action of any who have *inadvertently* not stated my meaning was a "serious" and improper thing to do. Mr. Debenham wrote (July 18th):—"Misrepresentation is a more serious charge than Mr. Berkeley seems to think; and, as he has not given any instance of what he calls 'misrepresentation' on my part, perhaps he will think proper to withdraw his charge—at all events as far as I am concerned."

It may be a matter of opinion, but I submit that Mr. Debenham's diction in the foregoing sentence is not calculated to make what I now see must have been his intentions clear. It would have been more plain to have simply written:—"As Mr. Berkeley has not given any instance of misrepresentation on my part, perhaps he will think proper to state that his charge cannot be—or is not—laid against myself." Then, to me, Mr. Debenham's word "charge" seemed too strong an expression to be applicable to any statement of an *inadvertent* misrepresentation on the part of others. I could not but feel that the words "serious charge" could not apply to any less accusation than that of "*wilful* misrepresentation."

Further: "at all events, so far as I am concerned," seemed to make it appear that Mr. Debenham considered that the "other writers" besides himself were improperly charged, but that he was only disposed to claim the withdrawal of the charge as applied to *himself*, leaving the other writers to act for themselves. I considered that perhaps Mr. Debenham repudiated the idea that I had been misrepresented by *anyone;* and being perfectly certain that I had been misrepresented by several I refused to withdraw the term, but, on the contrary, wrote at length to justify my use of it. I refused to withdraw the term as applied to the Editors and anonymous writers, but stated, as I thought, plainly enough, that "I did not include Mr. Debenham among the 'other writers.'"

Did not Mr. Debenham see those words in my last letter? Surely they bear no other interpretation than that no "charge" was preferred against Mr. Debenham at all.

I am glad to be able to make this explanation, for misunderstandings lead to "misrepresentations," and to satisfy Mr. Debenham so far. But he is to blame for not accepting my words:—"I did not include Mr. Debenham among the 'other writers.'" His tirade against me in his last letter was quite uncalled for.

I also wish to state that I used the word "incorrigible" in a tone of banter. I can scarcely believe that it is necessary to point out the significance of the seventh paragraph of my last letter (July 25th). I had explained that Mr. Pringle had endeavoured to fit a "cap on his head" that was not intended for himself. In a bantering spirit I wrote that Mr. Debenham was "incorrigible" no less than Mr. Pringle—the former particularly so, because any who had read Mr. Debenham's first letter (June 20th) in relation to the original matter I had broached *could not possibly have considered* that I included *him* among those who had "misrepresented" my writings, seeing that *he made no allusion to my opinions.*

If Mr. Debenham will refer to my letter of July 11th he will see that after I wrote—"like the other writers, the Editors totally misrepresent my meaning," I proceed to take these writers *seriatim*, and to point out where they are in error. I had endeavoured to dispose of Mr. Debenham's letter and objections to the "slip system" at an *earlier* stage of my letter, and here nothing was written as to Mr. Debenham having misrepresented me.

In my last letter, of which he now complains, I wrote—"I believe Mr. Debenham really *likes* some one to tread on the tail of his coat." But no; "*I did not include Mr. Debenham among 'the other writers'*" (note that). "I did not write 'all the other writers;'" but I acknowledge it would have been better to have written 'like most of the other writers.'"

What could have been plainer than these words? And what could have been fairer than my acknowledgment that my diction might have been better? I have no charge to substantiate, because I intended none; and none to withdraw, because none was made. The "charge of misrepresentation" against Mr. Debenham existed in his own imagination only.

I did *not* "put it" that Mr. Debenham had "no right to object to being accused of misrepresentation" because he "had stated that" he "had been misrepresented in certain reports in the Society's *Journal*" (I use Mr. Debenham's words). I put it that Mr. Debenham had no right to lecture me, as it seemed, upon the "serious" offence of "accusing" others *(not himself)* of misrepresentation, while *he himself* had not long before "accused" the *Journal* of the Photographic Society of "*misrepresenting*" *him.* I believe it is now clear that Mr. Debenham thought himself included among "the other writers," and therefore wrongly "accused," and that his objection was on that account. I am sorry that I did not understand him so.

I can hardly consider that I have applied "epithets" to Mr. Debenham. To say that he is "incorrigible" (in the sense in which I used the term) is at least not a very offensive "epithet." I may remind Mr. Debenham that offensive epithets can be hinted at as well as written, and that *he* is not behindhand in inferring *dishonourable* conduct in me.

My writing in connection with this subject and controversy, from beginning to end, has been so mauled and mangled by the several writers that in order to make my meaning clear to those who will not take the trouble to *read*—though they *write* upon—my opinions, I am compelled to occupy so much space upon a matter which, though entered upon in the public interest with most inoffensive and temperate suggestions, has degenerated, by no initiation of my own, into a personal contest between readers whose interests are really alike. Why cannot writers in this or other journals state their opinions upon a public matter without having anonymous attacks made upon their motives and general conduct? It is open to all to state contrary opinions, and by all means let them.

I shall send the promised answer to Mr. Debenham, on the subject of coloured images, next week.—I am, yours, &c.,

29, Southampton-row, W.C., Aug. 16, 1884. HERBERT B. BERKELEY.

Notes and Queries.

"Is a prism or a mirror best adapted for employment with a copying lens?—F. S. T."——We answer: If the angle to be included be a very narrow one the prism will be the better; but for general use, and more particularly for large angles, the mirror is to be preferred.

"WOULD you kindly, through the medium of your valuable Journal, inform me the best way to mount photographic prints on thin paper for book illustration, so that they will be flat and not cockle?—PRINT."——In reply: Let "Print" mount his photographs with india-rubber paste and he will find they will not cockle. This paste is merely a solution of india-rubber in benzole.

"Is there any patent existing by which I can be prevented from constructing and selling enlarging lanterns, the principle of which consists in having placed behind the negative a plate of ground glass strongly illuminated with gas from behind?—WORKSHOP."——In reply: Our correspondent is at perfect liberty to manufacture lanterns according to the principle stated, there being no patent existing which could operate to prevent him from so doing.

G. HERCUS asks:—"Will you favour me with a formula for an intensifier composed of red prussiate of potash?"——In reply: Try—

Nitrate of lead	4 parts.
Ferridcyanide of potassium	6 ,,
Water	100 ,,

The under-exposed or weak negative, having been fixed and washed, is placed in this solution until it has acquired the requisite opacity.

H. B. G. inquires—"What is an albatype plate?"——We reply: It is a thin metal plate having its smoothest surface coated with a fine white enamel or pigment. When first introduced this class of plate was employed instead of opal glass upon which to print by the collodio-chloride process; but, owing to some mismanagement connected with the selection of suitable albatype pigments, discolouration of the surface took place, and the manufacture of the plates was discontinued.

CHAS. S. STRETTEN experiences some difficulty in getting his sensitive paper at all times to lie in intimate contact with the negative, and asks for a remedy.——In reply: The remedy lies in interposing a sheet of elastic material between the paper and the back of the printing-frame. Let him employ a pressure pad composed of either thin felt or thick woollen cloth, and the elasticity of this will be sufficient to ensure the paper being pressed against the negative "without a wrinkle or a fold."

FRANKLIN says:—"Do you know anything about a new form of gas burner that has recently been introduced, the peculiarity of which consists in a mixture of air and gas being employed to render incandescent a thimble composed of platinum gauze?"——We reply that we *do* know something of this burner, having seen it in action under various circumstances. It is not improbable that we may soon have an article on this subject. We are at present trying its application to photographic purposes, for which we think it well adapted.

F. Goss says:—"I received a formula for the preparation of a developer for ferrotypes in which there was an ounce of baryta and one a-half ounce of protosulphate of iron. Upon dissolving these in a pint of water there is an immense amount of precipitate, even when I employ distilled water. Kindly inform me what is wrong."——We reply: there is nothing wrong. The barium and iron salts no sooner dissolve than they react upon each other, producing sulphate of baryta and nitrate of iron. The former, being insoluble in water, precipitates. It must be removed by filtration.

George S. King asks us to supply a formula for the preparation of a silver printing bath containing some other nitrate than that of silver, with regard to the advantages of which much was at one time written.——To this we reply: Both the nitrate of soda and the nitrate of ammonia have been recommended as an adulterant of, or addition to, the nitrate of silver. If the albumenised paper have been lightly salted try the following:—

Nitrate of silver	4 parts.
Nitrate of ammonia	4 ,,
Sugar	4 ,,
Water	100 ,,

The toning and fixing of the prints are effected in the usual manner.

"With respect to the poisonous properties of the salts of barium, I recollect once reading in The British Journal of Photography that all the salts were poisonous except the nitrate; and yet, upon looking over a classification of poisons, I find the nitrate, and not the carbonate, the poisonous nature of the latter having been specially spoken of by you. —Alex."——In reply: We are aware that some who are quoted as authorities include the nitrate in the list of poisons, while other equally good authorities exclude it. "Alex." will readily hold us excused for declining to make an experiment to decide the question for his gratification. With regard to the carbonate: it is said that it is not a poison *per se*, but becomes converted into one when dissolved by the acid in the stomach. If, therefore, we can suppose the absence of any acid fluid from the stomach, the carbonate, according to this opinion, must be considered innocuous.

Exchange Column.

Wanted, a first-class tourist camera, &c., in exchange for a first-class (new) half-plate burnisher.—Address, Chas. W. Appleyard, photographer, Miall-street, Bradford.

Will exchange cameras, camera stands, and lenses (one a Ross's), for tricycles or bicycles.—Address, Public Loan and Discount Company, Limited, 32, Russell-street, Liverpool.

Wanted, a landscape lens to cover whole-plate up to the corners, in exchange for a good tourist telescope, with strap complete, value £2 2s.—Address, Earnest Ellis, 17, Trinity-street, Ryde.

I will exchange a strongly-made trunk-bodied 10 × 8 studio camera, with rack movement, for a Moulton spray print-washing machine or for outdoor apparatus.—Address, W. E. Debenham, Massingham House, Haverstock-hill, London.

I will exchange a large slab of plate glass, 55 × 25 × ½ inch thick, for coating plates on, ditto 25 × 22 inches, air pump receiver, 8 × 12 inches high. Wanted, plate-boxes 7½ × 5 and 5 × 4, or small gas-fire or stove.—Address, S. Warburton, 12, Waverley-terrace, Leopold-street, Leeds.

I will exchange a whole-plate bellows-body camera, three slides, bellows-body, best maker, fit for studio, mahogany double-swing back, screw focussing, 1000 *carte* mounts, and a few dozen old *carte* and cabinet photographs.—Address, Mr. Kupham, 11, Victoria-grove, Kensington-gate, W.

We will exchange a 7½ × 5 bellows-body camera, rachet and pinion, focussing arrangement, swing-back and rising front, with reversing frame for oblong or upright pictures, six double dark slides for same, all in new condition. Wanted, twenty-inch focus rapid symmetrical lens, or offers.—Address, J. E. and C. Ireland, 14, Methven street, Perth.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

Photographs Registered.—

Messrs. C. and C. Fergus, 36, West Blackhall-street, Glasgow.—*Two Photographs of the Late Daniel Conway.*

Francis Hoare, Coxwell-court, Cirencester.—*Photograph of the "Cathedral Firs" in Oakley Park, Cirencester, Gloucestershire.*

William Pankhurst Marsh, Norfolk Cottage, Bognor.—*Photograph of Sands and Beach at Bognor (West Side of Pier), Sands and Esplanade at Bognor (East Side of Pier).*

Erratum.—In Mr. W. K. Burton's article on page 517, in the sixth paragraph, for "dish" *read* "desk."

W. W. and S. A. J.—We will communicate with you privately.

More Light.—Messrs. Chance and Co., Birmingham; or Mr. G. F. Williams, 36, St. Martin's-lane, W.C.

Benj. B.—Animal charcoal must be employed for the purpose. Your failure arises from your using charcoal made from wood.

J. W. K.—Not *absolutely* necessary with some samples of paper, but far better in every case. In all probability the washing will conduce to greater permanency.

R. S.—Why not apply two or three coats of Brunswick black? That will cover up the rust and preserve the metal—at least for a time, or until you can procure new trays.

J. A. Cundale.—Your communication should be made through the medium of our advertisement columns, as you publish no details of the process. It is purely a business matter.

H. J. Edge.—1. Better consult a respectable optician, who will supply you with suitable spectacles.—2. The larger lens would be very serviceable, but would not fulfil the same end as the spectacles.

A. Tisdale.—The idea appears very good, and, so far as we are aware, original; but we fear you will have some little difficulty in putting it into practice. However, the difficulties, we imagine, are far from being insurmountable.

Cosmos.—Very little consequence. One plan is quite as good as the other. Either way, a certain amount of skill and experience is necessary, as you are aware. As a rule, that plan is preferred with which the operator has had the most experience.

E. B. J.—If you forward us a few examples of your failures in printing we shall understand the cause (with the information you have given); but without seeing them we might possibly mislead you, as the terms you have employed are scarcely those adopted by photographers.

Arthur.—From what you say we judge the prints were sufficiently washed in the first instance. The spottiness appears to be due to the prints remaining moist for so long a time. The many days they remained wet has caused a decomposition of the sizing material of the paper.

H. A. Young.—The dark corners of the picture arise from the lens employed to take it not covering the size of plate properly. Instead of using it for half-plate pictures you should be content with quarter, as that is all it will cover thoroughly. Indeed, for its focal length, it is all that ought to be expected.

A. D.—The marks are caused by the action of the silver paper on the negative through its not being varnished. In all probability the film contained a trace of hyposulphite of soda upon which the silver has acted. There is no remedy now, unless a solution of cyanide of potassium will remove the stain, which is somewhat doubtful.

G. H. Brabazon.—From your description of the studio we do not see how it can be altered and improved without considerable expense, which, as you say your means are limited, we imagine you will be unable to incur. Possibly, if you were to raise the studio your neighbours would compel you to raise the chimneys also; hence you would be no better off.

J. Fox.—Asphaltum and marine glue are both very good as a coating for the insides of wooden trays; but the former material requires the addition of bees'-wax or similar substance to prevent brittleness, particularly in cold weather. We ourselves much prefer paraffine wax to either material when the trays are to contain solutions of nitrate of silver.

Meadow.—Possibly your friends employ more sensitive plates than you do. Drop-shutter exposures are frequently very successfully made with single lenses, and also with the "portable symmetrical;" but, worked with its full aperture, your "rapid" should be the quicker lens. We do not imagine that the lens has deteriorated as you surmise, but that your plates are not sufficiently sensitive for the work in hand.

Received.—S. D. McK.; H. Y. In our next.

Photographic Club.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 27th inst., the subject for discussion will be *The Artistic Mounting of Photographs.* Saturday afternoon outing between Highgate and Hampstead. Meeting afterwards at the "Bull and Bush" at 6.30.

The Recent Explosion at the Curragh.—In connection with this unfortunate explosion, the details of which were given in our issue of last week, we learn that the report of its having been a lime-light or oxyhydrogen explosion turns out to have been incorrect. It was alleged at the magisterial inquiry into the circumstances attending the unhappy event that the disaster was caused by an explosion of a pyrotechnic compound, consisting of chlorate of potash, sulphur, verdigris, and shellac. This mixture, when ignited, was intended to give a brilliant blue light.

Photographic Artists' Co-operative Supply Association, Limited. —The annual dinner of the *employés* of this Company took place on Saturday last, the 16th inst., the rendezvous being Weybridge, Surrey. An excellent repast was served at the "King's Arms," and, favoured with beautiful weather, a very pleasant and enjoyable day was spent. Mr. J. H. Keen (in the unavoidable absence of Mr. H. R. Faulkner, the Manager and Secretary) occupied the chair, and proposed the health of the directors, coupling with it the name of Mr. Faulkner, which toast was drunk with enthusiasm.

Artists and Pictures.—The papers which are just now going the round of the Royal Academicians, with printed inquiries as to the various modes of technical procedure resorted to by each artist, bring again into prominence the important question of the use of pigments, the durability and properties of "vehicles," and the different preparation of grounds. Particulars as to absorbent and non-absorbent ground-priming, and as to the varnish or exceptional pigments used, are asked for in these forms, which, if carefully and conscientiously filled up, should be of the greatest service to the profession at large. The present lamentable condition of many modern pictures should lead artists to give a more careful consideration to their pigments. The present state of Wilkie's "Blind Fiddler" is a remarkable instance of the fatal effect of ignorance or carelessnes in the use of paints which will not stand the test of time.—*Pall Mall Gazette.*

No. 1269. Vol. XXXI.—AUGUST 29, 1884.

HOW TO AVOID GRANULARITY IN COPYING PAPER PHOTOGRAPHS.

It is seldom that copies from paper photographs turn out altogether satisfactory, however skilfully they may be executed. This is owing to the fibre of the paper always showing more conspicuously in the reproduction than it does in the original. If, instead of the copy being of the same size as the original it happens to be made larger, the fibre is, of course, rendered still more painfully conspicuous by reason of the amplification; and, unless the picture be afterwards finished in monochrome or coloured, it is rarely, as most professional photographers know, that it gives entire satisfaction. The more granular the copy the greater, of course, is the labour of the artist in the finishing, and consequently the more expensive the reproduction becomes.

Many methods of ameliorating this excessive coarseness have at different times been proposed—such as mounting the print to be copied in optical contact with a glass plate; rendering the print itself transparent and then printing by contact to secure a transparency, and from that making a negative; copying the print with the lens slightly out of focus; and numerous other plans or "dodges"—all of which, though they may be theoretically good, still leave much to be desired when put to the test of actual working. The best plan, perhaps, in practice is that of copying the print when it is illuminated with a strong side light instead of a front one. This plan has more than once been advocated in these columns, and is, we know, now regularly adopted by many professional photographers.

We were recently shown some exceptionally-successful copies from paper prints which were produced by a plan that certainly possesses some degree of novelty; hence the reason for our again alluding to the subject. The copies—it may be explained—were enlargements from *carte* to cabinet size, and, although the amplification was considerable, as only a portion of the subject in the original was included in the copy, the grain of the paper was imperceptible. Indeed it was difficult to conceive that they were copies of paper photographs at all. The pictures were sharp, though not microscopically so, and had a brilliancy which copies rarely possess, unless the negatives have been elaborately worked up by the retoucher, which, we were assured, was not the case in this instance.

It may be remembered that a few years back some pictures, the productions of Mr. Denier, a Russian photographer, were shown in this country. These pictures were somewhat peculiar in their characteristics, and were decidedly pleasing. While no part of them appeared to be out of focus, yet they could not be considered absolutely sharp in the strict sense of the term. The lights were pearly and brilliant, and the half-tones soft and delicate; still this quality was clearly not due to the retouching of the negative.

The method by which they were produced was never published, or, at least, verified by Mr. Denier; but at the time it was currently reported that the prints were actually made from double negatives—one thin one being on the back of the glass and another on the front—or that they were printed from two distinct, but thin, negatives superimposed the one upon the other. Another method suggested as that by which they were done was that only one negative was used, and the peculiar effect was obtained entirely in the printing, which was accomplished in the following manner:—After the print had been about half-printed a thin piece of glass, or other transparent media, was interposed between the negative and the paper, and the printing then continued to the requisite depth. Whatever was the method adopted by Denier, we have produced results possessing the same characteristics as his, and equally good, by the method just described.

By this time the reader has, doubtless, began to wonder what the Denier pictures have to do with the copying of paper photographs? Well, a great deal in the case at present under consideration; for the excellent copies to which we have referred were produced by means precisely analogous to that just described. We learn the *modus operandi* was this:—In copying the original it was illuminated with a strong side light, so as to minimise the grain as much as possible to begin with. The negative was made tolerably vigorous, and then slightly retouched. In printing, when the impression had attained somewhat about half its proper depth, it was removed from the negative, and a couple of thin films of gelatine—such as those used in packeting confectionery—were placed upon it, one of these films being tinted a pale blue and the other colourless. The print was then replaced and the printing continued until it was dark enough.

The first printing appeared to have secured all the necessary sharpness and fine detail, while the second caused a certain amount of diffusion which destroyed the granularity without materially interfering with the definition in the more prominent portions secured in the first. Why one of the gelatine films should be tinted we are unable to say, for we should imagine that a colourless film of a corresponding thickness would answer quite as well; but we give the method as it was described.

When we learned the method by which these pictures were made we remembered having seen M. Lambert, in one of his demonstrations at which we happened to be present, adopt a precisely similar course in the case of a great enlargement, from a paper picture, which showed a considerable amount of granularity. After the impression was partially printed a sheet of patent plate glass, nearly the eighth of an inch thick, was interposed between the negative and the carbon tissue. The printing was then continued through the interposed glass to the necessary depth, and, by this means, much of the coarseness was destroyed, and considerable labour saved in the after finishing.

Of course, producing the impression by a double printing entails a little more trouble, and some method must be adopted for securing registration, as it is impossible to remove the print from the negative and replace it in exactly the same position when one or more films of gelatine intervene, with only the eye to guide us.

There are several forms of registering-frames to be had which will answer the purpose admirably. However, by a very simple arrangement, an ordinary pressure-frame will answer every purpose. All that is necessary is to secure the negative rigidly in one corner of the frame with a couple of slips of gum paper. The frame, by preference, should be one fitted with plate glass. The negative being secured, the paper must be cut so that its top and one side, at least, shall be from exactly a right angle. Now if, in placing the paper on the negative, care be taken that it is fitted accurately into the angle of the frame, it may be removed, the gelatine films introduced, and then replaced with the assurance that it will again occupy the same position on the negative—the same precaution, of course, being taken that it is fitted carefully into the angle of the frame as in the first instance.

A NOVELTY IN WORKING DROP SHUTTERS.

In our last issue we dwelt upon several points connected with the use of shutters for quick exposures, and indicated certain principles which should be adopted in their use, though they have rarely been acted upon. Whatever may be the theoretically-perfect form with which a snap shutter should be in accordance, it may be taken as a fact that, so far, such a form has not been made. All that have hitherto been constructed may be looked upon as compromises between accepted principles, the exact form having been governed by other factors than the inventiveness of the constructor. Some have been practical successes, and others literal failures. Most of us have seen the electric shutter which would not go, and there is many a photographer, no doubt, who could point out a mouldering glass jar and a rusty piece of mechanism as the sole relics of a few guineas' expenditure. There are all shades of usefulness between the practical worthlessness of this instrument and the success attending upon more simple contrivances.

We need scarcely remind our readers that the class of shutter more commonly seen is not the most complicated, though the more complicated patterns are not necessarily the less perfect on account of their intricacy. The truth is that they are very heavily handicapped in the race by the increased weight of the parts having a tendency to cause vibration during the action of exposing and closing. It is quite evident that many forms possessing features of usefulness might be devised if this particular property could be ignored; but, as absence of vibration is a *sine quâ non* in the use of a shutter, a certain amount of restriction has hitherto had to be placed upon inventiveness in this direction.

A well-known contributor to our columns has, however, shown to us a very simple arrangement which quite does away with the difficulties of tremor when the photographer can take a little extra trouble in his work. The additional apparatus is of the simplest description, and, so far as we can judge, will be a useful and eminently practical addition to any photographic outfit. It consists merely of a separate stand for holding the shutter, and is light, portable, and devoid of complication.

To construct such a one nothing is required but a portion of a bamboo fishing-rod, two brass ferrules such as are sold for ordinary fishing-rods, and two thin bars of wood a few inches long. The labour of an hour or two would enable anyone to fit it up. The two bars of wood—one twelve and the other six inches long, by two broad, and half-an-inch thick—form the foot, the smaller one being let into the side of the other so as to form a flat, T-shaped base. At the point of junction a circular hole is cut to form a socket, into which is fitted the handle of the bamboo rod (the two first joints only being used and the rest rejected), which has been trimmed so as to fit readily in and out of the socket. At the other end of the shortened rod the larger of the two brass ferrules is firmly fastened, and on to the shutter the smaller one. It is thus seen that the extra luggage required is merely a portion of a bamboo fishing-rod weighing a few ounces, and a small, light, wooden base.

To set up the apparatus the rod is pushed into the socket hole, the shutter with its attached ferrule fitted into the end of the rod, and, when the camera is fixed and all is ready, the shutter-stand is placed before the camera, and the inner rod—that to which the shutter is attached—moved up till exactly opposite the centre of the lens. A thin wooden wedge is then inserted to prevent the rod slipping down, and the whole is ready with the exception of making the junction with the lens, the mode of doing which we will describe.

The particular shutter employed was the Cadett "drop shutter," which, when used with some very light cameras, is apt to produce a tremor. It works guillotine fashion—an ebonite plate moving up and down in front of the lens—and at the back is a small curved piece of rubber-covered wood to fit the curve of the lens hood, the whole being fixed by a strong rubber cord, and the light kept out by a short velvet tube fastened round the lens by a piece of thin elastic cord and a button. To use the shutter in the manner described this latter arrangement would be useless, as the sole object is to remove the camera from the sphere of the influence of the shutter; consequently this piece of wood is removed. Further: the velvet sleeve also is taken away and replaced with a much longer one, so as to avoid the necessity for any very accurate adjustment of the shutter before the lens, as such a necessity would totally destroy the practical character of the arrangement.

When the stand and shutter are placed before the lens at the right height the velvet sleeve is slipped over the lens, and secured by the elastic cord or button; or it may be left unfastened, as the sleeve appears to fit quite light-tight enough without any special fastening. The fitting up and getting ready is the work of a few seconds only.

Our contributor informs us that though the apparatus is of the slightest description it yet answers perfectly and requires improvement only in two points. He would prefer to supply three sharp spikes or studs to the base to secure it more firmly on rough ground or long grass, and the sleeve should be provided for an inch or two of its length near the lens with a few cane or wire rings to keep it from swagging and possibly interfering with the field of view. He had not found it to do so, but he has thought it desirable to spend a little time in adjustment so as to avoid that defect; this time might be saved by the adoption of the rings. Though he has but recently fitted up the arrangement, which in its present form is more of a "makeshift" character, he informs us that he has used it on several occasions in photographing dogs, horses, and children, and is highly pleased with its action, the stand in each of these instances being placed either on a loosely-gravelled path or on a well-mown lawn. It is evident that he places faith in its usefulness or he would not have employed it (as he wrote us he did) on a recent occasion when taking a family group of the Premier and the whole of his family, including seven grandchildren.

It is for each of our readers to judge for himself whether the arrangement we have described is likely to suit his own particular class of work or not. Certainly it is cheap, simple, and light. We do not doubt that if it should be thought useful it will be made in one shape or another by the manufacturers of photographic apparatus, to suit those who have not the leisure or the inclination to make their own apparatus.

DIRECT LARGE PORTRAITS.

When, twelve years ago, the late Mr. Robert Crawshay offered prizes for a series of large portraits, which were to be taken direct in the camera, the result was a collection that elicited much more wonder than admiration. It was abundantly evident that the time for ushering in photographs of that class was not yet ripe. This was rendered still more apparent by an imposing display of *enlarged* portraits, which were also the same year submitted for competition, and proved the means of giving the *coup de grace* to direct-taken, life-size pictures.

Many, if not most, of the faults inherent in such portraits in those days arose from the necessity that existed for employing large portrait lenses, working with an aperture so great as to render uniformity of definition difficult, if not impossible, especially when, owing to the exigencies of dimension of the scale of representation, the sitter had to be brought unusually near to the lens.

As between a direct life-size photograph and an enlargement of the same dimensions there is clearly no comparison, the latter having the advantage. This was true in an emphatic sense in the times to which we have referred. It is still true, although in a more modified degree, at present, when, owing to the greater sensitiveness of the plates, portrait lenses of large dimensions are not now, as they formerly were, a necessity in connection with the production of large portraits.

Our readers do not require to be informed that in America the element of size in portraiture is more thoroughly recognised than it is in England; and in this connection they will peruse with much interest the graphic details, given by our American correspondent in another page, of the very large portraits he saw displayed at the exhibition connected with the Convention of the Photographers' Association of America recently held in Cincinnati. The account given by our correspondent—who, as a practical photographer, is well able to form a sound judgment—of the pulling about of backgrounds, cameras, and accessories, in order to show to the assembled hundreds in what way a large negative of a sitter was taken, is exceedingly amusing. Mr. J. H. Kent, the President, who is well known to excel in the arts of lighting and of posing sitters, undertook to give a demonstration of the method of taking a *large* portrait. How an hour was discovered to have been devoted to preliminary operations, how a 24 × 20 camera with a large lens attached got smashed, and how it was subsequently announced that for the large cameras no lenses could be got to suit—that the dark slides repudiated all connection with the cameras, and that even the plates were found playing at cross purposes with the dark slides—behold! is it not to be found narrated in the letter of our "special"?

But here arises the question—What difference is required in the artistic lighting and posing of a figure that is to be taken on a 24-inch plate, or even one much larger, and that on a plate which being only one half or one quarter such dimensions may therefore, by contrast, be designated a small plate? Emphatically none! The care and skill required in the posing of a figure are all one, whether the resulting picture is to be large or small; and this also applies to the lighting of the figure, the selection of a suitable background, and the introduction of appropriate accessories. Art is art in one case equally as in the other; and the artistic outcome of the demonstrator's skill in these essentials might just as well, one would think, have found expression in a 12 × 10, a whole plate, or even in a cabinet, as in a plate two feet in length. Indeed, the smaller dimensions would have proved most convenient to the greater number of photographers, as it would have served for illustrating the national journals, and thus have proved an educational means of more extended application than under other circumstances would have been the case. But it would seem as if in the plethora of cameras on exhibition there were none applicable for even the minor duty at which we have hinted.

It is significant to learn that these large direct portraits are not found to pay. The real "bread-winners," it is well known, are the portraits of moderate dimensions. Apart from the fact of there being more harmony and equality in the definition of the various planes in a small than in a large portrait, the cost of a plate varying from twenty to thirty inches in dimensions necessarily becomes somewhat high, while there is a far greater risk of the negative being imperfect on account of the sitter's having moved, or of manipulatory difficulties, than in a smaller plate, in which the extra expense entailed by having to give a second or even a third exposure is inconsiderable. When to these drawbacks we add the serious cost of a lens, camera, and general outfit for direct large portraits, and contrast all these with the excellence to be obtained in an enlargement from a good negative of small dimensions, it is indeed matter for surprise that there are those still to be found who produce large portraits direct, even for the sake of advertising.

However, if any photographers *will* "go in" for portraits of this class they have at the present period a consolation which did not exist at the time referred to in our opening remarks. They do not now require large and expensive portrait lenses, as was formerly imperative, to enable them to effect the end desired; because, owing to the greater sensitiveness of the plates, a class of lenses originally introduced for a different purpose may be relegated to the purposes of the portraitist, in fulfilling which function they are found to far surpass, in the excellence of their results, the more costly and cumbrous instruments they have superseded. To these, however, as they have of late formed subjects for comment in these pages, we shall not here further advert.

In his address delivered before the American Convention the President is reported to have said that the time was when the profession of photographer was not held in as high esteem as that of statesman or expounder of the law; but that at the present time quite a different condition of things existed. It is, we think, satisfactory to learn that in America, at least, photographers have attained a position of equality with "statesmen;" but the question remains to be settled whether it is by a process of levelling up or levelling down.

Some interesting details upon the properties of the sulphites of soda have been published in the *Comptes Rendus*, by M. de Forcrand, and from them we extract so much as will be interesting to photographers. In keeping solutions of pyrogallol and sulphite—the normal sulphite—of soda it is usually recommended to add some kind of acid to neutralise any alkalinity of the solution, the acid to be selected is usually said to be immaterial. The writer in question, however, states that a solution of sulphite of soda is partially decomposed by hydrochloric acid, for instance, the base dividing itself between the two acids, with formation of chloride and acid sulphite, in a manner similar to that observed by Berthelot in the case of potassium sulphite. To obtain a pure sulphite for experimental purposes a known weight of carbonate was saturated with sulphurous acid, an equal weight of carbonate added, and the whole put to crystallise in an atmosphere of nitrogen. The crystals contain seven molecules of water, which, it is found, is all given off at a temperature of 150° C.

In asking for sulphite of soda it is very desirable to "see that you get it." We know of many instances where, on the presumption that the purchaser was ignorant of what he really wanted, sulphate of soda was substituted by the dealer without remark. In other cases the sulphate has been supplied through the ignorance, or worse, of the seller; and we know as a fact of one instance where an amateur going to a chemist's for a-quarter of a pound of sulphate of soda was supplied with "hyposulphite," the seller calmly informing him that he had made an error and that the latter was what he wanted. Taking the chemist's word he added the salt to an ounce bottle of pyro. He did not achieve any success in his development with this fluid, and when we informed him how the matter stood he seemed annoyed with the chemist.

It is expected that the "Inventories" of next year will surpass in interest either the "Fisheries" or the "Healtheries." No doubt photography will play an important part there, and would-be exhibitors must remember that only a month now may elapse before applications for space will be too late—the 1st of October being the last day for sending them in. The inventions, excluding music, will be confined to those invented or brought into use since 1862. No charge will be made for space, and motive power will be supplied free; but gas and water will have to be paid for, if used. It is a satisfaction to know that one element of the shopkeeping character will be abolished, as exhibitors and their assistants will not be allowed to invite visitors to purchase their wares.

The Liverpool Astronomical Society, at their third annual meeting, recently held, had a good account to give of work performed. The work done for the last twelve months had been mostly stellar photography. The large camera had been set up in March, and from some of the plates the catalogue of stars recently published had been taken. Attention had been given to the photographing of star-clusters and nebulæ; but the most important work had been the comparison of star magnitudes, and for this purpose photography had been largely used. Every month certain stars were photographed, and if any change appeared a systematic observation was at once commenced, several such observations being carried on at the present time. As our readers are aware, this Society is and has been doing real, substantial work; and it is gratifying to hear of the part played by photography in the work of a society whose home is a city that has always been in the van of photographic inventions and progress.

Professor Bischoff's spongy iron filter is an admitted success for purifying water; but experiments show that a portion of the iron is dissolved and carried away in the effluent water, thus rendering it unsuitable for photographic use. The principle has been adopted on a large scale in Antwerp for the town's supply, the water having been filtered through a mixture of the finely-divided iron and gravel. An improvement has lately been made upon this system, as it was found it would be too costly on an increased scale; the water is now passed through a revolving cylinder containing the iron and a series of shelves or ledges for scooping it up. We draw attention to this fact more especially to show the chances of water being contaminated with iron, as the inventor of the system states that when water was in contact with the iron for forty-five minutes it was very heavily charged with that metal. When a much larger quantity of water was passed through in the same time it still issued containing 1·2 grains of iron per gallon; and even when sixty gallons passed through per minute nearly one grain of iron per gallon was dissolved. It is thus evident that no system of iron filtration of water would be likely to be suitable for photographic purposes—a fact which is rather unfortunate, seeing that very complete purification otherwise is effected by such means, water so purified being almost freed from ammonia and nearly as colourless as distilled water.

It is well known that chloride, as also iodide, of silver is capable of forming a precise chemical compound with ammoniacal gas, but hitherto the compounds have not been obtained in any definite form. Lately, however, according to the *Bulletin de la Socièté Chemique de Paris*, M. Terreil has obtained them in a crystalline shape. To do this he introduces them in their amorphous form, along with a saturated solution of ammonia, into a flask sealed at a lamp, and then exposes the whole to the temperature of boiling water.

Our contemporary, *La Nature*, describes a process of "photography without apparatus," which may not be entirely beyond the reach of their non-technical readers. It is founded upon the action of light upon bichromated albumen. The reader is directed to obtain two pieces of glass, clear and flat—to paste upon one a sheet of thin black paper with a square aperture in it, and to join the two plates by an elastic band at two opposite ends. A few pieces of albumenised paper are to be purchased, and sensitised by coating the back with a six-per-cent. solution of bichromate. The prepared sheets, it is explained, will keep for several days. The photograph to be reproduced is to be removed from its card by soaking in cold water for twenty-four hours, and then drying between folds of blotting-paper. Then this "*cliché*," as it is now termed, is placed, face upwards, within the square formed by the black paper; next the sensitised albumenised paper, face downwards, upon it; and the papers kept *in situ* by placing the second plate of plain glass over all, and binding the whole together with the elastic bands. The next step is to expose to light for about twenty minutes, until an image appears at the back of the albumenised paper. Taking the arrangement into a darkened room, the paper is removed and placed in a deep dish filled with rain water, so as to dissolve out the unacted-upon albumen. The next step, after spreading the print upon a sheet of glass and allowing it to drain till almost dry, is to flow over it a quantity of ordinary writing ink, taking care not to let it dry upon the shadows, for the action is very quick. Then it is again washed gently for about as long a time as was required to dissolve out the bichromate. The image should now appear of a violet colour, which takes a warm tone by a prolonged exposure to light. It is quite permanent, seeing that it is produced by an actual colouration of the coating of albumen, certain parts of which have been rendered insoluble by the action of light, while the rest only absorb the colouring matter, which is retained by the interstices thus created. The process is summed up by saying that it consists simply of—1. The sensitising of the albumenised paper in a six-per-cent. bath of bichromate. 2. The exposure of the proof to the sun until the image appears at the back of the sensitised paper. 3. The washing of the proof and its development with common ink. "What is most remarkable," *La Nature* states, is the fact that "by a single operation a positive proof is obtained from a positive." Further: the colouring agent (the ink) can be replaced by any other coloured substances, though the ink is both best and simplest. Our readers will know the difficulties that must attend every step of this apparently-simple process; still, at the same time, it may be said that there is no reason why presentable copies might not be obtained under favourable circumstances by the unskilled reader.

THE LATE MR. C. JABEZ HUGHES.

The late Mr. Jabez Hughes, whose decease we announced a fortnight ago, and whose portrait we present in the present number, was interred on the 14th instant at Abney Park Cemetery, side by side with his only son, the late Alfred J. Hughes, and within but a short distance of more than one old friend. By the special request of Mrs. Hughes the arrangements were made as quietly as possible, and consequently the ceremony did not partake of the public character that would have been expected in the case of one so well known and universally esteemed as Mr. Hughes. Her Majesty immediately upon hearing of the death addressed an autograph letter of condolence to Mrs. Hughes, and also forwarded a beautiful wreath for the coffin. The latter was of polished oak, and bore at the foot a plain brass plate with the inscription:—"Cornelius Jabez Hughes, died 11th August, 1884."

The late Mr. Hughes was born in London in 1819, and when quite young took great interest in debating societies and similar associations. He became a lecturer and teacher on memory, and in that capacity made the acquaintance of Mr. J. E. Mayall, then in business in the Strand as a daguerreotypist, whose secretary he became, and with whom he obtained his first knowledge of photography. After remaining two or three years with Mr. Mayall, Mr. Hughes in 1849 established himself as a daguerreotypist in Glasgow, purchasing the business of Mr. Barnard, in Buchanan-street, which he raised to the front rank in that city. Though strictly a daguerreotypist during his sojourn in Glasgow, he adopted and worked the collodion process to a small extent soon after its introduction. In 1855 he returned to London and commenced business as a photographer in the Strand, working here nothing but the collodion process; but this venture not proving a success, in 1859 he opened a warehouse in Oxford-street. He was one of the earliest to recognise the future field for photography which the "*carte* mania" foreshadowed; and, as the business of a dealer was not congenial to his temperament, he cast about for a new opening as a photographer. This presented itself towards the end of 1861, when upon the death of Mr. Lacy, of Ryde, the business was offered for sale, and Mr. Hughes became the purchaser, being succeeded in Oxford-street by his friend and previous manager, Mr. John Werge. He very shortly afterwards rebuilt the studio and reception rooms in the Arcade, Ryde, erecting in their stead the handsome suite of business premises that have since become recognised as amongst the most perfect in the kingdom.

His contiguity to Osborne and the high-class character of his productions secured for Mr. Hughes the patronage of the Queen, for whom he executed a large amount of work. One of the latest pictures taken for Her Majesty, a copy of which is in our possession, consists of a group of twenty figures—composed of the Queen, her children, and grandchildren. By order of Her Majesty Mr. Hughes produced a series of portraits of the late Earl of Beaconsfield, which are said by those who were personally acquainted with the late Earl to be the most truthful portraits of him produced in late years.

Ever ready to avail himself of what seemed to be improvements, Mr. Hughes some years ago adopted the carbon process to the almost entire exclusion of silver printing from his establishment; new forms and sizes of pictures were also readily taken up if they possessed the features of artistic novelty.

The death of his only son in 1878 was a great blow to Mr. Hughes, and since that time he had never recovered his old business energy, though he was seldom absent from the meetings of the societies, much of his time being spent in London. His long photographic connection with the metropolis had necessarily familiarised him with all the societies, in the management of most of which he had taken part. We find his name on the committee of the now defunct North London Photographic Association up to 1862; he was on the council of the Parent Society from 1866 to 1871 inclusive, and again from 1876 until last year. He was also a vice-president of the South London Photographic Society from 1873 until the time of his death; and, though not an officer of the Photographic Club, he presided at the inaugural meeting, journeying from Ryde for the purpose, and never missed the ordinary meetings when he happened to be in town. He was, in addition, one of the oldest members of the Solar Club.

In connection with the literature of photography Mr. Hughes was also well known; for, in addition to the numerous papers read, and articles contributed to our columns, he was a constant speaker at the various meetings he attended, being ever ready to share with others the knowledge his extended experience had given him. There was not a branch of photography—scarcely a branch of science—on which he was not qualified to speak; and the fluency of his diction combined to render his discourses especially interesting and instructive.

But the chief work by which he will be remembered is his *Principles and Practice of Photography*, originally published in 1860, and which has run through many editions. This is, perhaps, the most complete practical instruction book that has ever been published in connection with photography, as, while dealing with every branch of the science, it gives descriptive details without

prolixity and without shirking minor points, while it is a model of conciseness.

Our portrait is an ink-photo. from a photograph taken in Mr. Hughes's own establishment at Ryde, I.W.

AIDS TO THE ADVENT OF THE CAMERA OF THE FUTURE.

There is much that is useful and suggestive in the recent articles by Mr. W. H. Harrison and Mr. Andrew Pringle on the subject of increasing the effectiveness of the portable camera, and we take up the theme by way of keeping such a desirable ball in a state of motion; for out of a full discussion of the subject something of practical benefit is certain to result.

By way of classifying the various qualities that ought to be possessed by the tourist's camera, we commence with one the value of which will be evident to every one who has been out in the field: we allude to *rapidity of unlimbering*. We have seen a photographer take quite as much time to undo the straps of his case, get the tripod-stand put together, and the camera unpacked and placed *in situ* ready for action, as it did for another pleasure-seeking party in that vicinity (Epping Forest) to alight from a conveyance, unpack sundry hampers, spread a cloth upon the ground, and arrange all the preliminaries for the enjoyment of a substantial *al fresco* dinner.

It is not quite easy to say in what way the camera and appliances should be packed, because the packing-case which would prove sufficient when the scenes of the pictorial campaign lay at no great distance away from home would be inadequate for the Himalayas, the Alps, or the Rocky Mountains. For home work we have seen a very convenient, cheap, and strong case, capable of containing camera and six double slides, made of thick pasteboard or thin millboard, as follows:—The tail-board of the camera ($7\frac{1}{2} \times 5$), which was sufficiently long to suit a lens of long focus, was kept distended, but the body of the camera was pushed close up to the front. When in this condition the case was so constructed as to receive it when placed side lowermost. This left a large square space unoccupied, in which was fitted a canvas satchel containing the six dark slides, leaving still space enough to accommodate the camera top, focussing-cloth, and other odds and ends.

The case, we have said, was formed of thin millboard; but it was lined, both inside and out, with cloth such as that employed in the covering of books, this having been pasted on with thin glue. The lid was attached to the back by a strip of stout linen which acted as a hinge, and it had a ledge round the front and sides about two inches deep. The front of the case was hinged at the bottom, so that when the cover was raised the front fell down, exposing the interior to view through the top and front. It is useless to speak of *minutes* in connection with the opening of the case and lifting out the camera; for it was only a matter of seconds, and very few even of them, three motions of the arms serving to open the case and remove the camera.

The lens was attached to a front capable of being reversed in position, by which, when thus reversed, the lens itself was placed inside of the camera, safe out of the way of harm. The whole time occupied in its reversal was five seconds, which included the undoing and refastening of a strong bolt that ensured the lens being securely fixed. The extension of the camera body was effected by means of a simple sliding motion, which could be arrested at any stage by pressing a brass button. A fine adjustment, consisting of about an inch of rackwork, could then, if requisite, be brought into operation by the action of the finger and thumb upon the milled head of a brass nut. But when the subject to be photographed was such as not to necessitate the employment of the swing-back, then the focussing was effected by merely sliding out the camera body to correspond with a small black line on the base-board. This having been determined for objects at a distance, an oblique line, graduated by experimental trial, served to ensure the sharp focussing of objects closer at hand. A folding sight on the top served to show the amount of subject included by any of the lenses belonging to the camera, so that should an accident befal the ground glass one need not discontinue working in consequence. It only remains to be said that the dark slides do not "slide" in, but are stepped-in from behind into a suitable recess, in which they are held by means of a spring.

The camera, as thus described, although not a commercial article, has been exhibited at certain of the societies and clubs of the metropolis, since which time, however, an improvement has been effected in that portion of the base-board by which it is attached to the stand. This, instead of being single, as before, has been made double to a small extent longitudinally, yet so as not to add to the thickness of the base-board. The head of the stand is attached to the outside portion, which, in turn, is fixed to the main base-board by strong hinges at one side with a stop, by which it is capable of being turned over on its side after having been erected on the stand; and in this way the picture (in the case of a panorama) may either be taken with the plate placed horizontally or lengthwise to the horizon, or be immediately thrown on its end should a tall spire in the vicinity prove a more attractive subject at the last moment, and all this without undoing a single screw.

We leave it to our numerous friends interested in this subject to say to what extent the camera here described comes up to the ideal camera of the future.

PHOTOGRAPHY IN BELGIUM.

[From Our Special Correspondent.]

Brussels, August 26, 1884.

Attention was drawn in my last to the general isolation of British photographers in the matter that comparatively so few interchange visits with their professional brethren on the continent. The objections frequently urged of difference of language and expense were then examined. Another objection sometimes urged against an autumn vacation abroad is that of sea-sickness. The sea is not usually rough in the autumn, but one way of cheating it of its due is, when the weather is rough, to wait one or two days at the English port and cross when the water is smooth. Another plan is to make the horrors of sea-sickness as brief as possible by crossing by one of the two short routes. The average time of crossing by Dover and Calais is seventy minutes; the average time by Folkestone and Boulogne is eighty minutes. The latter passage is nine miles longer, but in going to Paris it shortens the railway journey on the other side of the Channel by about thirty miles. All the boats are exceedingly fast. The "Mary Beatrice" on the Folkestone line is claimed to be the fastest vessel afloat. A rival and perhaps an equal in speed is the "Violet," between Holyhead and Dublin. The distances being short, the passengers many, and competion strong, expense of coals is no impediment. On these Channel boats men are incessantly stoking all the way across. Two of the boats between Harwich and Antwerp are propelled by twin screws. These boats are not only fast, but the engines have not the best part of the ship, as in paddle boats. The passengers are placed amidships, and this reduces sea-sickness by about one-third. In the centre of a see-saw there is much less rising and falling motion than at the two ends. Just so is it with the position of passengers when they can occupy the space usually allotted to paddle engines. In time none but twin screw boats are likely to be used between Harwich and Antwerp. The boats leave Harwich every week night about ten o'clock, and usually after a comfortable night's rest the passenger wakes up in time for breakfast as the steamer makes its way up the river Scheldt to Antwerp. The lace-like spire of Antwerp Cathedral is seen across the flat country long before the city is reached. Antwerp is about one hour from Brussels by rail.

The Relationship of Photography in Belgium to the State.

At the present time, among the public placards on the walls of Brussels are some announcing that a series of fifteen experimental lectures, to educate in photography those who choose to attend, are given at the Royal Museum of Industry. There is no charge; these lectures and others on scientific subjects are delivered at the expense of the State. All the would-be learner has to do is to enter his name and address. In the more free countries of Europe great care is taken by some of the States that if any of their sons possess ability, no money impediment shall stand in the way of their obtaining the highest education they are capable of receiving. In Switzerland a boy fresh from the plough can, if he wishes it, find door after door of the mansions of education freely opened to him one after the other, if he can and will give a few years' time and application, until at last he has a thorough university training. At the Polytechnic Institute at Zurich he can learn professions useful to him in life, such as civil and mechanical engineering, chemistry, the scientific aspects of agriculture, forestry, and so on. As in practically learning chemistry and other scientific subjects he must use up materials in his experiments, he has to pay for them a fixed sum of four pounds a year and that is all; the time he has to devote to the study of the selected subject is three years. With broad generosity the Swiss Government has not limited the benefits of the institution to its own subjects, but admits young men of other nations without raising the terms to them. A few English students have taken advantage of these facilities, and many from Italy and Austria. Preliminary examinations have to be passed to obtain admission.

Facts like these serve to give some idea of the degree of civilisation attained by nations versed in the art of self-government, and to show that Belgium does not stand alone in placing a good scientific education freely before all its subjects for acceptation.

The Professor of Photography and Chemistry at the *Musée de l'Industrie*, at Brussels, is M. L. Rommelaere, who, in his younger days, pursued his studies at the University of Ghent. After completing those studies he worked at that University without remuneration for pure love of the occupation, and afterwards received his present appointment in Brussels.

The following is a translation of a circular issued early this year to the people of Brussels:—

"ROYAL MUSEUM OF INDUSTRY.—LESSONS ON PHOTOGRAPHY IN 1884.

"Public and gratuitous lessons on photography will be given, as in previous years, at the Royal Museum of Industry, by M. Rommelaere, chemist to the Museum. They will commence on Thursday, June 5th, 1884, at half-past three o'clock, and will be continued on following Saturdays, Mondays, and Thursdays, at the same hour.

"As for practical experiments the times will be decided hereafter, in order as much as possible to suit the convenience of the majority of the listeners.

"In order to give more attention to the numerous discoveries and processes brought forward of late years, the Minister of the Interior has decided that the number of lessons, previously fixed at twelve, shall be increased to fifteen. The following is the programme:—

"I. History.—Summary of the different processes in use.

"II. Light.—Its physical and chemical properties.

"III. and IV.—Photographic apparatus. The optical portions. The cases. The camera and its accessories.

"V., VI., and VII.—The negative process. Wet collodion. Dry processes on paper. The gelatino-bromide process.

"VIII., IX., X., and XI.—Positive processes. The salts of silver. Enlargements. Proofs without silver. The products: their preparation; their assay. The carbon process.

"XII., XIII., and XIV.—Industrial processes. Photolithography. Heliotype. Photo-engraving. Enamels.

"XV.—Scientific applications of photography.

"An important collection of choice instruments gives the power of making the lessons more clear by experiments and demonstrations. A library, entirely at the disposition of those who enter their names for the lectures, consists of works relating to photography, and of prints of all kinds obtained by the different processes.

"It may be stated, in relation to the object of the lectures on photography, that they are useful to all—as much to those who desire to learn the first principles as to operators who already understand the manipulations but who desire to learn about the newest inventions and the latest improvements.

"The endeavour will be made, above all, to popularise by explanations and experiments all the applications, which are growing every day more important and numerous, of photography in industry, the sciences, education, and art.

"The necessary augmentation of the number of lectures demands that three shall be delivered per week, in order not to prolong the total period given to this subject, as well as to meet the wishes of the majority of the listeners.

"For admission to this course of lectures on photography it is sufficient to enter one's name at the house of the Director of the Royal Museum of Industry, Place du Musée, Brussels."

The whole establishment having been formed for the benefit of the public, individuals among the latter may, under certain necessary restrictions, make use of the chemical and photographic laboratories at the Museum to carry on their own researches. They have to satisfy the authorities they know how to use the apparatus they wish to employ and are not likely to injure it. They have to pay for any damage done, and for any chemicals or other materials they use. In some cases where the individual is not well known he has to deposit a certain amount of money as security. Some of the instruments are of great value. The microscope, for instance—a magnificent instrument by Dallmeyer—cost somewhere about £200.

The site of the Museum was originally a small lake, which was filled up in 1336 by the Seigneur Devenvoorde to erect a mansion. This building was subsequently enlarged and became the residence of the governors of the Low Countries. It was renovated and enlarged in 1731 by the Duke of Lorraine, who gave it its present aspect.

The *Musée de l'Industrie* was reorganised under a royal edict, dated April 7th, 1841, in consequence of its previous inadequacy to encourage scientific research, and the application of scientific principles to practical purposes. A National Library existed previously, but the library of the present Industrial Museum consists solely of scientific and artistic books which may be consulted by day, and in the evening up to ten o'clock. It resembles the English Patent Office Library, except that the latter closes at four o'clock, and is inaccessible to the industrial population after their working hours are over. The Brussels Industrial Library is in the same range of buildings as the chief National Library. Gas is burnt in it, in which it differs from the British Museum Library, warned by the irreparable loss to the world, due to the destruction of the Alexandrian and other libraries by fire. On the other hand, the books in the Industrial Museum at Brussels are such as, for the most part, can be at any time easily replaced. The building is solidly constructed of stone, with very little wood, and one of the city fire engine stations is on the premises. The chief National Library is not in the same wing of the building. When the Industrial Museum was reorganised it was placed under the control of a permanent committee of ten persons, several of whom were large manufacturers with works in various parts of Belgium; in 1841 they elected as their president M. Fréderic Basse, member of the Provincial Council of Brabant. At the same time M. Jobard, engineer, was appointed director by the Belgian Government. In the following year, 1842, the Industrial Museum began the publication of its *Bulletin*, which has all along been rich in information in relation to the progress of the arts and sciences. Its first number contains the translation of an article by Robert Stephenson, on Derrider's locomotive.

The "installation," as it is called here, of M. Rommelaere, for the teaching of photography and chemistry, consists of three lecture theatres, a chemical laboratory, and a variety of large rooms well stocked with apparatus and fixed appliances for experimental work. The wooden end of one of the lecture theatres can be raised or let down by mechanical means, allowing those in the theatre to see the whole interior of the adjacent laboratory, and between the two halls there are arrangements for carrying off, by means of a chimney, any chemical fumes which may be either poisonous or objectionable. In one wall of the laboratory are also a variety of small furnaces and muffles, with arrangements for carrying off the fumes; the upward draught of air in the chimneys is produced by burning jets of gas. In this laboratory the chairs and tables only are of wood; everything else is as much as possible of brick, iron, or stone, to avoid danger from fire to the national library close at hand. The ceiling is of stone. The laboratory contains a water tank, from which water may be obtained at a more even pressure than direct from the mains. There are several pieces of apparatus in this laboratory, by which ninety cubic centimetres of water may be boiled in three minutes for experimental purposes, by means only of the single flame of a Bunsen burner. The principle of construction is such that the heat of the flame is distributed over a large surface of metal, in contact on the other side with the large surface of a small quantity of water. The even pressure of water in the laboratory is used when desired to produce a current of air to urge a blowpipe flame; it is also used to produce an imperfect vacuum quickly. There are several Sprengel pumps on the premises—one of them with glass joints, to give a good vacuum when required.

During the past season 230 persons attended the lectures of M. Rommelaere on photography, among whom were eight or ten ladies. As the light of the sun falls on one side of the lecture theatre in the afternoon, apparatus is sometimes fixed in one of the windows to exhibit experiments with the solar spectrum.

There are many rooms in which physical and other apparatus is stored under glass cases. There is plenty of electrical apparatus of all descriptions, including a large induction coil which will give a spark fifty centimetres long. A barograph and a thermograph are also on the premises.

An instrument for exhibiting to a public audience the method of recording meteorological changes by photography consists of a paraffine lamp, the light of which is collected by a plano-convex lens and sent through the upper part of a barometer or thermometer tube. A lens on the other side sends the image of part of the tube with the level of the mercury through a long wooden tube, until it falls upon a photographic screen moved by clockwork, which thereby registers the changes in the level of the mercury during twenty-four hours. A gelatine plate, from thirty to forty centimetres in length, is usually employed to register the indications. The total length of the apparatus is two and a-half metres.

In a room in the lower part of the building, devoted to specimens connected with the iron and cotton industries, are some remarkable specimens of what appear to be pieces of sculpture in solid stone, but are in reality but sheet zinc coated with oxide of zinc and silicate of soda. It resists the action of the weather exceedingly well; indeed, with it a man may make a carved stone front to his house at little cost, and almost carry it away on his shoulders, like another Samson, should the design displease him.

The valuable Dallmeyer microscope already mentioned is used for photomicroscopic work, and arrangements are made for directing and controlling the light of the sun upon its field of view. In the same room is a superb instrument for photo-spectroscopy, made by Hilger, of London. It contains six prisms of Iceland spar, that substance having but little power of absorption of the chemical rays. Iceland spar, being like chalk in chemical composition, is very tender; the whole instrument is, therefore, kept in a case nearly air-tight to protect it from moisture and acid gases in the atmosphere. The prisms would be difficult to clean if soiled, so M. Rommelaere gets over this objection by not attempting to clean them at all. A portion only of the case is usually removed when the instrument is in use, the remainder of the case then serving to partially screen the instrument and the eye of the observer from extraneous light. This spectroscope rests, like an astronomical telescope, upon a stone pillar. Three pieces of steel, with highly-polished hollows at the top, are let into the stone pillar; the three feet of the spectroscope rest in these polished steel cups. The spectroscope is thus maintained in a truly firm and horizontal position. It gives a spectrum about a yard long, such is the amount of dispersion, and shows two lines between the two sodium lines. The floor of the chamber in which this spectroscope stands is of tiles, which rest on the solid ground.

Photography was first recognised by the Belgian Government in 1870, when M. Rommelaere received his present appointment. He teaches engineering drawing, as well as chemistry, photography, and physics, and those who learn mechanical drawing at his classes usually obtain appointments in works as soon as they have attained proficiency.

Specially delicate balances are employed in the establishment. Some of them are so delicate that they have to be protected from the heating effects of light when in use; also from the heating effects of an adjacent human body in particular positions in relation to the weighing apparatus. M. Rommelaere has devoted much attention to the investigation of the chemistry and properties of the platinum group of metals. At one time he gave great attention to the collodio-bromide emulsion process, and says that he is convinced that it can be made to produce as rapid results as the gelatine process. He has several developing-rooms on the premises. In an open yard is apparatus on a turn-table for taking photographic copies of the valuable paintings in the national collection. This turn-table is at the back of a large case with glass front, in the open air, containing a restored gigantic skeleton of an iguanodon, which seems to be a connecting link between birds and reptiles. It carries its head like a bird. Brussels has the only skeletons of these as yet unearthed, except that a leg bone, or some other bone of one of them, is in London.

M. Rommelaere took the chief part in founding the Belgian Photographic Association. He has translated into French one of Captain Abney's works. The translation is published in Brussels under the title of *Cours de Photographie.*

At present men's minds in Brussels are deeply agitated about politics. Next Sunday there will be a public procession here of tens of thousands of persons, to request King Leopold II. not to sign the nearly-passed law for placing the public schools within the influence of the clerical party.

A CHAPTER IN THE HISTORY OF COLOURED IMAGES.

I now redeem the promise made in my letter (July 25th) that I would answer Mr. W. E. Debenham's queries and objections to a communication of mine which appeared in the May number of the *Journal of the Photographic Society* partly in relation to coloured images produced by means of bromide plates. I would have done so earlier had I not been away from home.

Mr. Debenham (July 18th) makes it appear that I claimed in that letter that I had originated and published a method for producing coloured images upon bromide plates. I flattered myself that I had stated plainly enough what I could prove to be a fact, viz., that it was *not* "Mr. Wellington who first *produced* colours on bromide plates."

Mr. Debenham's statement, as reported at a technical meeting of the Society, was that it is Mr. Wellington who "first *produced* (not published) colours on bromide plates." In my letter to the *Journal of the Photographic Society* I simply stated that this was not so, but that I, among others (I claimed no "special early knowledge"), had produced various colours on bromide plates, including gelatino-bromide, as early as the year 1877 (in truth 1876), and that I could bring proof of the correctness of my statement. I laid no claim to priority of publication. Mr. Debenham writes (page 462, July 18th):—"Mr. Berkeley refers to having published the matter some years earlier." I challenge Mr. Debenham to quote any words of mine to that effect. I confined myself to writing that *my* "knowledge on the subject dates from as far back as about seven years ago."

But Mr. Debenham is apparently determined to place me in as unfavourable a light as possible ("give a dog a bad name," &c.), and does not write fairly; indeed, his unfairness is only equalled by his loose reading of my letters. I did not, as Mr. Debenham writes, "refer to a *print*" in the possession of Captain Abney, but to a *negative*. This Mr. Debenham might have seen on reading Captain Abney's footnote (see page 132, *Journal of the Photographic Society*, where the latter writes:—"It was a negative showing a group of oxen"). Captain Abney is in error; but this error should be quite unimportant. This negative represented a *single cow*. I have stated this because if the negative should be still in existence, and it should be necessary to identify it, the truth on this point might be important. Captain Abney goes on thus:—"The sky was almost crimson" (ruby or claret-coloured I called it) "by transmitted light." Your readers will gather that it was something rather out of the ordinary way, even at a more recent date, if I say that Captain Abney, after a public exhibition of it at a technical meeting, thought it worth while to ask me whether he might retain possession of it as an *example of colour* in reduced silver.

Now, it is not everyone who *admires* "claret-coloured" pictures, whether positives or negatives; and as for myself, since I was interested in the production of *negatives* by various means, I did not attempt to apply my knowledge to the making of coloured *positives*, whether desirable or not. Let me here say that I consider that Mr. Wellington is entitled to some credit in departing from the usual groove, and in producing upon bromide films the tints Dr. Eder had produced upon chloride, and upon the lines laid down by the latter for the sole and peculiar treatment of the chloride; also in publishing his method of so doing. [It must not be forgotten, though Mr. Wellington may be quite unacquainted with the fact, that in a controversy I had with Dr. Eder in the columns of the *Photographic News* I stated that colours *could* be produced upon *bromide* films equally as upon chloride; and Dr. Eder had shown how to produce them upon chloride plates. The method of production, therefore, had been pretty plainly indicated—not that "iron development" is necessary to obtain brilliant colours, since "pyro. development" with fine bromide films in the powdery condition will also give rise to them.]

Mr. Debenham touches upon other points. If he will turn to volume xxiii. of this Journal he will find, in the number for February 4th, 1876, page 58, towards the end of a letter of mine, that my theory was "that chloride of silver has less sensitiveness to the less refrangible rays than the bromide;" and "that in a 'well lighted,' open view chloride would follow close upon bromide of silver." On other occasions, too, I have reiterated my opinion that chloride is particularly affected by the more refrangible rays. [See also the last paragraph of my letter referred to.] That my view was not a mistaken one we now know; and we have Captain Abney and Dr. Huggins using chloride in preference to bromide for scientific photography where a selective sensitiveness to the blue is particularly desirable.

No doubt I modified my views from time to time, as most experimentalists do, if they are worth anything; and I have written both highly and rather disparagingly of silver chloride at different times. The words Mr. Debenham places between brackets (page 463, July 18th) make it appear that I only *suggested* that silver chloride would be more sensitive than bromide "when a proper developer was *discovered*," whilst it remained for Dr. Eder to publish any *practicable* method of development.* If Mr. Debenham really infers this he is in the wrong, for I showed that silver chloride in gelatine could be *satisfactorily developed* by alkaline pyrogallol. I also showed that silver chloride in albumen (albumenate of silver was present, the paper being sensitised upon a bath of silver nitrate and washed) could be successfully developed by what I stated was the "hydrosulphite developer," but which I have since had reason to believe was a hydrosulphite of soda developer with sodic hydrate produced by means of metallic zinc.† The method of making and developing the chloride paper (as well as bromide) I described. It was very simple and perfectly successful from a photographic point of view.

As regards the comparative sensitiveness of silver chloride and of silver bromide under *suitable* conditions: it may be said that this still remains a moot point. There are arguments and facts which may well lead the best among us to take somewhat "mixed" views on the matter.

Then, as regards the use of "excess of silver:" Mr. Debenham would find, if he took the necessary pains, that I have written both for and against the use of "excess of silver" nitrate in gelatino-bromide. Even that point still seems to remain moot, if we accept the evidence of recent writings on the subject. The fact is that circumstances alter cases very much, and the same thing may be good or bad under different conditions. Mr. Debenham may like to make it appear so, but there is really nothing derogatory to myself in having upheld views which are not at the *present time* generally accepted. It may be, too, that my views, quoted by him, may still turn out correct; it may be that they are delusive; but *at the time my words were penned* my views were as far advanced as those of any other writer on this particular subject.

Mr. Debenham would do well not to try to pin me down to any writings of mine of several years ago without acquainting himself with whatever I have more recently written on the subject in hand, but at, perhaps, almost as distant a date. For instance—whether rightly or wrongly time will show—long before most of the present writers had any ideas at all on gelatino-bromide work I *publicly* condemned the use of excess of silver nitrate in making gelatine emulsion, though a method involving its use had previously been worked out and advocated

* Dr. Eder's method is really a step backwards so far as the application of chloride to *camera* purposes is concerned.

† The following particulars may seem out of place; nevertheless they may not be amiss:—Contrary to the apparent opinion of the Editors at the date of the publication of M. L. Sammann's method (January, 1877), bisulphite of soda cannot be kept in the form of crystals; and solid salts that may be purchased as "bisulphite" are in reality, at least mainly, the "neutral" sulphite. It decomposes thus:—

$$2\,SO_3HNa = SO_3\,Na_2 + OH_2 + SO_2.$$

Further: the Editors gave directions that the solution of bisulphite should be made neutral to test paper, so that the "free acid" (?) should be eliminated. Now, to make a solution neutral to test paper would be to make the solution *mainly* composed of the "*neutral" salt*—not entirely, for the "neutral" salt is alkaline. The sulphites at the time referred to were not familiar to me; and, as is too commonly the case, I am afraid, I ordered a supply both of "neutral" and "acid" salts from a well-known London firm, and trusted that I had the "genuine article." To cut a long story short I am convinced that this was not the case. The action of metallic zinc upon bisulphite is presumably as follows:—

$$\underset{\text{Sod. bisulphite.}}{3\,SO_3\,H\,Na} + \underset{\text{Zinc.}}{Zn} = \underset{\text{Zincic sulphite.}}{Zn\,SO_3} + \underset{\text{Sod. sulphite.}}{Na_2\,SO_3} + \underset{\text{Sod. hydrosulp.}}{SO_2\,H\,Na} + \underset{\text{Water.}}{OH_2}$$

zinc sulphite and sodic hydrosulphite being produced. The action of zinc upon the neutral salt is thus:—

$$\underset{\text{Sod. sulphite.}}{SO_3\,Na_2} + \underset{\text{Zinc.}}{Zn} + \underset{\text{Water.}}{2\,OH_2} = \underset{\text{Zincic hydrate.}}{Zn\,(HO)_2} + \underset{\text{Sod. hydrate.}}{Na\,HO} + \underset{\text{Sod. hydrosulp.}}{SO_2\,H\,Na},$$

sodic and zincic hydrates and hydrosulphite being produced. There is no zincic salt in solution, but the white hydrate adheres to the metallic zinc. It would appear that a developer made by the latter method owes its energy largely to the presence of sodic hydrate, and that, time being allowed for the reaction and weight for weight, the neutral sulphite would produce the larger quantity of hydrosulphite. The bisulphite, though, is far the more soluble in water. The foregoing will explain how it came about that the developer contained sodic hydrate.

by me. This will show how misleading are the insinuations of Mr. Debenham in the matter he somewhat unnecessarily introduces into his letter.

It is no easy matter to go through the whole of my writings during a period of over ten years; but sometimes, when turning over the pages of an old volume of the Journal—or, as at present, having to look up my own writings therein—I find "ideas" put forward by me which might, perhaps, even be termed "luminous." Thus, I just notice the following; and if anyone cares to turn to page 335 of the volume for the year 1875, and to page 83 of that for the year 1876, he will find that I indicated the use of decoction of cloves for preserving gelatine emulsion, and, further, was the first to use and to publish the use of chrome alum for preventing frilling. At the latter date I wrote:—"I believe I have succeeded by a method not before published in this connection;" and I proceed to show how I used one per cent. of chrome alum as compared with gelatine, and to state the result—prevention of frilling without loss of sensitiveness. How much chrome alum is even still used in the preparation of plates most of us know; and we further know how many at one time stated that it destroyed sensitiveness. But I am digressing. My object has been to try to illustrate how little many of us are aware of what was written years ago.

While I am now writing I am looking up what I have written upon the production of colour in bromide or chloride plates. On page 57 of the volume 1876, I write:—

"I have found some difference in the colour of negatives produced by bromide and chloride of silver; the latter inclines to a bluish-grey, metallic colour, while the former is warmer in colour. It is exceedingly likely that under different conditions of development a change of colour would be apparent. In the plate I shall mention further down—that developed with the smaller quantity of soluble chloride—the reduced silver is very clear* and metallic" (steel-coloured).

It will be seen that I showed that of two emulsions, prepared as similarly as possible of bromide and of chloride of silver, the *former* gave the warmer tone, and thus rather indicated—as for further reasons I held out, subsequently, in reply to Dr. Eder—that warmth of tone was at least as much an attribute of silver bromide as of silver chloride. I also showed that *reducing* the amount of soluble chloride in the developer made the tone *colder*—made it "very clear and *metallic.*" My readers will know that Dr. Eder and others now produce *warmer* tones by *increasing* the quantity of restrainer.

I have incontestably shown at the beginning of this communication that in this letter to which Mr. Debenham takes exception I laid no claim to *publication* of a method by which coloured images could be produced. I had merely to show that Mr. Wellington was not "the first to *produce*" various bright colours on bromide plates. However, there is no reason now why I should not state further what I find is a fact, viz., that I did publish the method by which such results could be obtained by using a pyro. and sesquicarbonate of ammonia developer, such as had (April 21st, 1876) been recommended by a writer of *nom de plume* of "Franklin."† I direct Mr. Debenham to the foot of page 203, and to the third paragraph of another letter of mine, page 250 (both 1876), but more particularly to the paragraph at the bottom of next page (251). I there stated that "I believe that the colour of these negatives is much more determined by the kind of developer used than by the process of their preparation." (This has reference to free haloid or free silver nitrate in excess. Fineness of division, I stated, did influence the result.) I go on:—"It seems to me likely that the red-brown colour is not caused by the action of silver in excess, but by the carbonate developer; for the hydrate gives an image not to be distinguished from that of a 'Kennett' plate, except by its density," &c. The plates referred to were those which had lately been introduced independently by "Franklin" and myself, and prepared with excess of silver nitrate. (See also second and twelfth paragraphs of letter, page 274.) There was nothing, therefore, to prevent anyone from producing negatives or positives of varied tints, either with ammonic carbonate or ammonia, or with a combination of both of these. I have at other times stated the colour of images obtained by other developers and plates. I may add that I stated my objection to the sesquicarbonate of ammonia—that it induced frilling on the plates I then made.

Mr. Debenham thinks it "unaccountable that the matter was not taken up and made much of at the time, and largely employed since." Is every valuable matter, then, "taken up," even at the present time? Further: does not Mr. Debenham know that at the time to which I allude "gelatine" was a by-word with most amateurs, and probably with all professional photographers. The process was worked at only by a few enthusiasts, and the general body of photographers, who might now "largely employ" a gelatine process for positives, had not then developed their first *negative* in a similar material. Old readers will be aware that many points in dry-plate work were published eight or ten years ago which scarcely received passing observation, but which, had they been announced at the present time, would have created a "sensation" at the photographic clubs and technical meetings. Even at the present day how difficult it is to get any to take up the simply *published* methods of another! It is generally necessary to force a method or production upon a community, and this is generally to be done only by introducing them commercially. Very practical directions for producing coloured images upon bromised collodion plates have been published by a variety of writers—among them Major Russell, Colonel Stuart Wortley, and Mr. Wm. Brooks; but no sensation has been created, neither has "the matter been taken up" or "made much of."

I do not think that any good end would be served by going more deeply into my writings, though among these—which are very voluminous, and contain, as I am now able to see, many valuable suggestions and facts—may be found further reference to coloured images. I do not know that I am entitled to much credit. I have shown that "Franklin" produced images of a somewhat similar nature, though whether he produced tints as brilliant as some obtained by me I am uncertain. I have only intended to show that I did *more* than "produce" coloured images, having also *published* eight years ago, or more, the method by which others might have done the same. I have proved more than I originally attempted to state. Readers of the present day may now have some conception of the reason I had for objecting to Dr. Eder's statements that colours could not be produced by silver bromide to compare with those to be obtained by iron development on chloride plates.

But here is another "appalling" letter! May I hope that Mr. Debenham will rest satisfied with it? HERBERT B. BERKELEY.

* Instead of "clear," "*translucent*" would have been the more correct term.

† "Franklin" stated that ammonia carbonate and pyro. gives a negative of a light drab colour by reflected light, and of a rich reddish-brown by transmitted light.

PHOTOGRAPHERS' ASSOCIATION OF AMERICA.

FIFTH ANNUAL CONVENTION.*

[FROM A SPECIAL CORRESPONDENT.]

August 4, 1884.

THE side gallery overlooking the Winter Garden was filled with screens covered with photographs, while the walls had their share of the display.

Along the edge of the balcony overlooking the garden was a very fine show of negatives, so arranged that the light was reflected through them. These negatives were made upon Cramer plates and were from various studios, but most of them were Mr. Cramer's own work. They were of large size and of first-rate quality. Here also was a very fine display of transparencies of large size made on Mr. Carbutt's special transparency plates, which are gelatino-albumen; and on a screen at the side of these were a large quantity of photo-mechanical prints, by Mr. Gutekunst, of Philadelphia, made upon Carbutt's stripping plates. These mechanical prints are as near perfection as it is possible to attain. We have nothing in England that can compare with them, either in perfection of result or cheapness of production. In this gallery was the very large exhibit of the President of the Association, Mr. Kent, of Rochester, N.Y., which was worthy of him and his position.

It would be tedious to your readers if I were to enumerate all the exhibitors separately; so I will only notice those which had some feature of general interest to photographers. One exhibit in this same gallery was remarkable, showing, as it did, that the results were due to the man and not to the plates. Mr. Dixon, of Toronto, Canada, was the exhibitor. The pictures (views) were about the finest in the Exhibition, and were all equally good. The plates used were those of two English and two American makers. Thus, with four different kinds of plates, Mr. Dixon had produced results which could not have been more uniform if they had been taken with one brand of plate. This should be an answer to those objectors who say that the introduction of dry plates would do away with all individuality in photography.

There were not many exhibits showing special rapidity in exposure. Mr. Armstrong, of Milwaukee, had some very quiet, artistic pictures, many of which must have had very rapid exposures. They were the only pictures in the Exhibition which showed any attempt at artistic composition of figures in landscapes taken at one exposure. The *Lone Rock by the Sea*—a male figure looking over the water—was most artistic; and, although the ripple on the water showed that the exposure was of the shortest, there was no sign of under-exposure in the figure. Another was *Tired of Browsing*—some cows on a hillock overlooking water, one of the cows standing on the top, outlined against the sky, while the others are below in the shadow; yet there was nothing harsh in the outline of the one nor want of detail in the others.

Close to these was a screen which deserved more than a passing notice. It is covered with examples of the platinum process of Mr. Willis. This process has found a great deal more favour in America than in England, and is almost exclusively used as a basis for finished work. The enlargements exhibited on this screen by Hoyt and Siebert, of New York, from negatives by Sarony and others, are very fine indeed. They are made in the solar camera and by electric light. The price is very low—a 20 × 16, mounted upon a stretcher covered with calico, being only nine shillings, and an 80 × 52 £5. They are nice to work upon either in crayon or pastel, as there is no gelatine or other sizing to make the working uncertain or difficult. I was surprised to find a process invented in England and little used there so well established here.

* Concluded from page 540.

From this gallery some half-dozen stairs take us into the picture and art-galleries. Facing the top of the stairs Mr. Carbutt had a number of pictures by different artists upon his special plates, for which he claims great rapidity. The claim would appear to be substantiated, for here are groups of cows taken by an amateur (Dr. Howe, of Philadelphia) with a drop shutter; and here, also, are the famous pictures of the bicyclist coming down the steps of the Capitol at Washington. In this room are the largest photographs I have ever seen. When in England I thought a great deal of manipulating 24 × 20 plates, but here are three-quarter lengths on plates which must measure fifty inches! Mr. Cramer exhibits some fine direct large pictures; but it was remarked by more than one that his negatives showed more detail than the prints from them. In the same room were exhibited Mr. Guerin's pictures, which took Mr. Cramer's first prize. I am not aware who were the judges, but there were many knowing looks and winks when it was explained that the plate-maker who gave the prize and the photographer who took it hailed from the same town. In fact, there is so much dissatisfaction expressed in this connection that I think the dry-plate makers will not offer prizes another year.

Taking the Exhibition altogether it was a most magnificent display—far surpassing anything I have ever seen in England. It was conspicuous for the great number of large direct photographs, which would have gladdened the heart of the late Mr. Crawshay. But, in talking with the producers of these large pictures, I gather that they do not pay for the outlay for the apparatus, except as advertisements; for they agree that the public would rather pay fifty dollars for an enlargement finished in crayon than thirty dollars for a direct photograph the same size.

This Exhibition has decided the question with regard to dry plates. America has been years behind England in the use of dry plates, and very few photographers have discarded the wet process altogether; but this year, as far as I could see, there are no examples of wet work exhibited at all. And, as it is universally admitted that this Exhibition was better than any before, it must prove to the most sceptical that dry plates can be made to produce results equal, if not superior, to the wet process.

While all agree that the Exhibition portion of the Convention was a decided success, it is also equally well agreed that the Convention, *as a convention*, was a total failure. Photographers who had travelled hundreds of miles to hear discussions and papers upon photography have little patience with the way the time of the members of the Convention was wasted by squabbles over the election of officers, &c. This feeling of dissatisfaction found vent in two meetings which were held at the Palace Hotel on the evenings of Wednesday and Thursday, July 30th and 31st, at which it was decided to have a meeting in the Music Hall the morning of Friday, August 1st, to discuss matters photographic *although the Convention had been formally adjourned* till next year at Buffalo. Accordingly, at eleven a.m. a bell was rung all over the building, and the meeting called to the platform under the skylight. Here it was seen that the President and one or two others were pulling about backgrounds, cameras, and accessories, and some hundreds of photographers and their wives sat and watched for *something* of interest or instruction to occur. The first thing that did turn up was a camera stand, upsetting a 24 × 20 camera with a very large lens and smashing the front of the camera. After this mishap there was more pulling about of backgrounds, screens, and cameras. A gentleman was seated before one of the backgrounds and a great deal of pulling about of all kinds of apparatus ensued, the only effect of which appeared to be that all the gentlemen on the platform got "mixed," and the sitter seemed very miserable.

At last, after nearly an hour of this, watched with great patience by the large gathering of photographers, Mr. Kent came to the front of the platform and said:—"It was intended to give a demonstration of taking a large picture this morning; but I find that there are no lenses that will suit the camera-boxes. We have no slides that will fit the cameras, and no plates that will fit the slides; so we must give it up." After this humiliating confession the audience quietly dispersed; and this was the only attempt made at the Convention to give a practical demonstration of anything photographic except those of a purely business character, such as the dark-room demonstrations of the various dry-plate makers and Mr. Seavey's illustrations of the use of his backgrounds and accessories in posing the sitter.

Mr. A. L. Henderson, of London, was a visitor at the Convention, having arrived from England to be present at the meeting of the British Association at Montreal. He must have been gratified at the reception he received, and it was most amusing to see how the dry-plate makers got round him—like "flies round a honey pot"—comparing notes and trying to get "points," as they say here. It is a proof how widespread is the circulation of THE BRITISH JOURNAL OF PHOTOGRAPHY that there did not appear to be many of the photographers present who had to ask who Mr. A. L. Henderson was. It must have been very trying to the patience of Mrs. Henderson to have to wait at almost every step, while one or other of his American admirers stopped her husband and kept him engaged in animated conversation upon topics photographic.

Of the routine business I will say nothing. You have had the details and papers in due course. I will only add that the President for the next twelve months is Mr. Landy—a photographer of well-known excellence in Cincinnati. His work exhibited at this Convention was of very high quality, and his large direct pictures were, in my opinion, the best in the whole collection. The place of meeting for 1885 is to be Buffalo, N.Y.

ON THINGS IN GENERAL.

ENGLISH photo.-aëronauts will have to look to their laurels. It is all very well to take a maplike view of any place that the wind in its caprice may blow you to, but it is quite another thing to pack up camera and plates, take your seat on the deck of the "helical" balloon, be steered where you will, take snap "shots" at whatever you like, and return in time for afternoon tea, being deposited, if you please, at your own dressing-room window. Such, in effect, is promised, or, rather, stated to have actually taken place. The Aëronautical Society of France having from their own grounds started their aërial car, its occupants took a sail of a couple of miles to windward and returned in five minutes by means of the simple expedient of turning the rudder. So far the French account. The advantages of this new plan of aërial locomotion will be considerable to photographers. When the express service is thoroughly established it will be so easy to take a balloon to any point and avoid all that careful packing which occupies such time when preparing for a long railway or road journey. But more than this: a single lens will suffice for the balloonist who "goes in" for maps of the country. He need no longer hesitate as to taking a battery of lenses, for he can get the exact range of view with one lens only by altering his altitude, free from fear of losing his view by the balloon's shifting. But, perhaps, I am getting on too fast. The balloon is stated to be able to go where it likes; but we do not hear if it can stay when it gets there—an important consideration.

Another point exercises my mind in the matter. Am I to believe it all? The French papers are full of it, and details are promised—a few weeks after the event—but on this side of the Channel a few paragraphs are all that the papers devote to the subject, and they are not of a very sanguine cast. Even our good friend, the editor of the *English Mechanic*, who always allows plenty of room to aërostation projects, gives a very guarded paragraph only, and refrains from saying more till he obtains further details. "We shall see what we shall see."

Many photographers remember the surprise caused some considerable number of years ago by the discovery of a small acarus actively enjoying itself and living heartily in nitrate of silver, the luscious crystals being evidently to its taste. One is thus prepared to receive with equanimity the account given by Mr. Sutton the other day of an inroad of black beetles upon his gelatine films, a whole batch having been ruined by the argentous proclivities of these affectionate creatures, who, not content with the near presence of their benefactors, even carry their fondness so far as to follow them in the amusements of their leisure. There is more in a black beetle than meets the eye. But even the actual presence of a cockroach in a store of plates would be preferred by most photographers to the mere inspection by "a young lady in the next room," be she ever so pretty, of the contents of the dark slides to see the "pictures that had been taken," such having been the experience of one of the members of the St. Helens Photographic Society on a recent photographic expedition in Lymm. The experience much reminds one of the latest photographic story in the *Detroit Free Press*. An amateur came to his mentor for an explanation of the faults of his plates, and, after a long series of questions and answers, the latter all tending to show that everything was right—"How did you know they were spoiled?" said the teacher. "Oh! Mrs. Butterwick was here, and she wanted so much to see how the baby took, and I opened the cases, and there was not a sign of a picture on any of the plates!"

By-the-bye, as there seems some talk about the "gradual change" of the "half-plate" size from the old $6\frac{1}{2} \times 4\frac{1}{4}$, I looked into an antique catalogue a quarter of a century old, and the only size I saw approaching the half-plate was $6\frac{1}{2} \times 4\frac{3}{4}$. I am sure that "half" of the old Daguerre size (16 × 22 centimetres), which I saw in a catalogue dated 1843, is nearer the modern half-plate than it is to $6\frac{1}{2} \times 4\frac{1}{4}$. Somebody has blundered.

The public would like to know something more about the vandalistic structure in Trafalgar-square. I have seen dog-kennels, or even the abodes of the more humble quadruped abhorred of Mahomedans, built far more in accordance with artistic propriety than this latest addition to the National Gallery. Who erected the affair? Government or a private speculator? Will the copies taken therein possess any copyright? Why, if the pictures were to be photographed, was there not public notice? I think I know several photographers who might have been glad of the opportunity to photograph if they only had been aware of the power to have a studio handy; and such a studio! I thirst for information! I do hope someone will be able to allay my thirst.

That was shabby treatment which the County Court judge was reluctantly compelled to mete out to the Liverpool photographer the other day. He had made an excellent enlargement from a poor photograph; but, through some such promise having been made when the commission was given that the picture need not be kept if not liked, the purchaser exercised his caprice and did not "like it," and so got out of payment. His Honour, however, did not fail to tell him what he thought of his conduct. I should like this judge to have a few more photographic cases to adjudicate upon. A County Court judge is supposed to see more of the seamy side of human nature than most people; but if a few leading photographers cared to bring before him some of the cases where they were victimised by persons whose dress and appearance would suggest ladies and gentlemen, he would have his eyes opened to little meannesses and deceit which even his experience could not parallel. Many sitters seem to think that a photographer's studio is like a lottery or a boot and shoe shop; the photographer to spend all his time and trouble, do his work well, and still take his chance of being paid nothing if the caprice of the sitter should lead her to say she "does not like it," and returns the photograph as though it were a pair of boots that did not fit, or, more properly, whose "cut" was not liked. Professional photographers will have to bestir themselves yet, or the public will get the whip-hand of them and command their own terms. Tht next move will be to go the rounds of the photographers, receive proofs, pick the one most liked, and decline to pay for the rest.

FREE LANCE.

WHERE TO GO WITH THE CAMERA.

[It is hoped that this series of articles will be continued at regular and frequent intervals during the vacation months, and we shall be glad to receive contributions to the series from any friends able to treat of new and interesting ground.

WINCHESTER, PORTSMOUTH, AND BOURNEMOUTH.

STARTING from Waterloo last year, about this time, for Winchester, Portsmouth, and Bournemouth, with a half-plate camera and a companion of good conversational powers, a fortnight was most pleasurably passed. Arrived at Winchester station, the omnibus quickly deposited us and baggage at the Black Swan Hotel, situated in the High-street and close to the George Hotel—a more pretentious house. A walk round the city and through the cathedral satisfied us that in two fine days we should capture all that pleased our fancy.

Before going further let me recommend all brother camera men to see Mr. Savage's studio, situated a little outside the city. A drawing of the angle of his garden wall appeared in the ALMANAC some years ago. The studio, which communicates with the house, is situated in the midst of a well-kept lawn. Upon entering the residence, and in the porch, is observed a German motto bidding you welcome. After your visit to the studio is over, you are conducted out by another door, and this time the motto wishes you good luck—or good-bye.

The exterior of the cathedral, taken as a whole, is photographically disappointing; still there are a number of interesting "bits" in and about the cathedral and college yards (they run one into another)—curious archways, old and mouldering, partly covered with vegetation.

The City Cross dates from the time of Henry VI., and contains several figures. Amongst the chief are William of Wykeham, King Alfred, &c., the Blessed Virgin, and other saints. If the cross be photographed with a wide-angle lens the modern building now occupied by Mr. Tanner, bookseller, can be avoided, and an old-fashioned gable-ended house comes in as a background.

The Guildhall—a most handsome building—would do credit to a larger and more important town. The front is well worth a plate. It is lower down the High-street than the cross. Proceeding across the river, the bridge weir next claims attention. Then passing on up the hill or cliff, if fine, a good view of the city can be obtained, taking care to get in some object close on the foreground, if only the stile and hedge. Hyde Abbey, through Jewry-street, is but a ruin, partly used as a farmyard. One of the heads on an arched gateway represents King Alfred.

St. Cross Hospital is worth a visit and one or two plates, especially if some of the brethren of St. Cross, in their black cloaks with a silver cross, and the brethren of Noble Poverty, in red cloaks and cardinals' hats worked thereon, can be secured also. This is the place mentioned by Dickens as "cakes and ale," each traveller being presented with a horn of ale and a cake with a cross upon it. Beaufort's Tower in the quadrangle, taking in the sun-dial pedestal, makes one good picture.

Winchester Castle forms another subject; but, alas! the great hall only remains of the old castle. Oliver Cromwell had been here, and, as usual, blew up the place. Here they show the "round table" of King Arthur.

Hursley churchyard contains the hallowed remains of John Keble, author of *The Christian Year*. The stained glass windows are said to have been given out of the profits of the book. Merdon Castle is close by—a small ruin.

There is one old gateway in the city still remaining. You pass under it going to Mr. Savage's studio, and I was told there is a fine early Norman gateway at the Roman Catholic church, brought from some ruins near the cathedral. Doubtless, the visitor will find or hear of other places of interest.

I may mention that at most of the hotels in the country, "boots" or the landlord will find a man who knows all over the city at one shilling the first hour and sixpence an hour afterwards, or four and sixpence the day. He will also carry anything without extra charge. It is difficult to obtain permission to photograph in the interior of the cathedral, and even with dry plates considerable time is consumed; so it is best to purchase these pictures from the local stationers, who keep an excellent collection of photographs.

To Portsmouth the railway passed by Havant and thence through the line of fortifications that surround Portsmouth. It was exceedingly wet when we were there, and photography was not attempted; but sufficient was seen to show that a batch of interesting pictures might be secured. Book to the *town* station, and if possessed of more luggage than will go on the tram, take a cab to the George Hotel, High-street. Trams pass the station every few minutes—fare twopence to any part of Portsmouth, Landport, Portsea, or Southsea; and if the tram does not go sufficiently far, or not in your direction, at Cambridge junction you can change and go on with the same twopenny ticket another mile or so. Few of the trams have any "upstairs."

In Portsmouth harbour are to be seen and visited Nelson's ship, the "Victory," also two other gallant ships—the "Wellington" and the "St. Vincent." The George Hotel is interesting, as in room No. 15 Nelson slept the night before departing for his last and final victory. Captain Marryatt has made us familiar with Portsmouth; and at the Keppel's Head—so called after Admiral Keppel—situated on the Common Hard, we find the house so well known to midshipmen, who call it "The Nut"—slang for "head." The dockyard is worth a visit; but I am afraid no photographing would be allowed.

The floating bridge is worth a plate, either to make a foreground for the harbour, with the "Victory" in the distance, or by itself. When I passed over it there were in addition about a hundred passengers, ten carriages with horses, small trucks, &c.; fare either a halfpenny or a penny.

If catching a few yachts, yawls, fishing smacks, or steamboats be desired, Southsea pier is the place *par excellence*, and for a trifling sum one may get aboard some of the larger craft and go out towards Spithead or down the Solent; or you may take the steamer to the Isle of Wight. From Southsea pier, however, can be obtained pictures all day long, forming food for the camera; also a good view of the beach, with a portion of the pier as foreground. Here can be watched the landing and departure of the steamers for Ryde, Cowes, and other places; and sometimes the Channel fleet is anchored off Spithead. A concert is given on the pier most evenings by a military band.

From a few notes, taken as a guide for future work, I find—"Take tram for Gosport and Brockhurst. At the latter place note the windmill; this, with a glimpse of the shipping in the harbour, can be seen, the tall spars standing up well against the sky. Also notice three curious trees in front of an old cottage, and some old fortifications, now overgrown with grass, but converted into dwellings—the chimneys and the streets all on one level."

There is an interesting bit of wall at the end of High-street and close to Victoria Pier; it commemorates the landing of Charles II., and forms a wind screen at the same time. The Mitre Hotel is an old-fashioned, gabled house worth a plate, and the church behind it, St. Thomas's, covered with ivy, but difficult to photograph.

I am sorry to say so little about Portsmouth, but I have indicated what a great deal of work there is to be done there. Several obelisks, in memory of fallen comrades, are scattered about the place, and these, when with a pile of cannon, make effective pictures; but do not introduce figures into these subjects.

Should the visitor run over to the island, at Ryde, the Royal Kent Hotel will be found near Mr. Jabez Hughes's royal studio.* To this day I remember a splendid salmon steak I had for breakfast at that hotel.

From Portsmouth there are two ways of going to Bournemouth—by water to Southampton, or by rail to Basingstoke, through Southampton West and the New Forest. A visit to Southampton will please; and, if this be decided upon, book to the Dock station. The Dolphin or Crown Hotels are both good. The Bar-gate is a very old gateway still spanning the principal street, and the town is divided as "Above Bar" and "Below Bar." A tram runs under it. Southampton docks are poor, and the town looks empty since the P. and O. boats have ceased to call there. I am told the harbour is considered one of the finest in the world, but it is not used to any extent. The city walls are worth notice. They are found to the left of the High-street coming from the docks, and lead to Southampton West station, whence we start for Bournemouth.

I might here mention that about a station before coming to Southampton there is a farm cottage, with an old water-wheel, and several rural "bits" might be easily picked up there.

To resume: after leaving Southampton West we soon reach the New Forest of Hampshire; but the only place that calls for notice is Lyndhurst road, with its pretty hotel—a celebrated place for newly-married couples to spend their honeymoon. Ringwood, Lymington, and Christchurch are passed on the way; and shortly afterwards the train steams into Bournemouth East station, the 'bus takes you to the Pembroke Arms Hotel—the headquarters of the Cyclist Club. When I was there a new hotel was being built at the Firs Glen, and this will be much more central. The Branscombe Hotel, a temperance house, I can also recommend; here will be found a *table d'hôte*. Bournemouth is known as the "ever green valley of the south." ARCHER CLARKE.

(To be continued.)

* Since this was written I deeply regret to hear of the decease of this estimable gentleman.

FOREIGN NOTES AND NEWS.

On the Recovery of Emulsion Residues.—Photography in Public Libraries and Museums.—Actinic Action of Light in Deep Sea Regions.

Lieutenant David and Herr Scolik have presented a report to the Photographic Society of Vienna, in which they give the result of their experiments on the recovery of silver from gelatine residues and the bath used for fixing gelatine plates, &c. This report is substantially an extract from *Photography with Gelatino-Bromide of Silver*—a work which these gentlemen have at present in the press:—

"As in the case of all other photographic silver processes, in working the gelatine emulsion process one should never lose sight of the recovery of silver from waste and residues. In the cloths used for pressing, the canvas bags, the empty cooking vessels, glass beakers and filters, there is more silver than in the paper filters and substrata that used to be so carefully collected in the wet process. The developer and washing water, on the contrary, unlike the wet collodion process, contain no silver at all, while the greater part of the silver used for the plates is to be found in the fixing bath. Indeed, according to Professor Eder's computation, they contain from seventy-four to eighty per cent. of all the silver used, only from sixteen to twenty per cent. being actually used in the formation of the image. We have found the recovery of this residue simplified and facilitated by the following procedure:—We collect all the fixing baths of both negative and positive process in a large cask. All the other residues, consisting of spoilt emulsions, filters, cloths, bottles, and also the films of dry plates that have become useless, we treat with hot water, in which the gelatine that contains the bromide of silver is easily dissolved. This solution we throw into the cask beside the old fixing baths, by which the silver compound is dissolved out, and the gelatine, being so extremely diluted, can no longer stiffen. We then place some brightly-scoured strips of zinc in the cask and leave them for a few days, at the end of which time the silver is precipitated from the solution; the clear, brownish fluid above it may be poured off and the silver precipitate left behind treated with hot water to remove any particles of gelatine that may still remain. The precipitate is then collected upon a filter paper and dried. It is as well also, before washing and drying the precipitate, to treat it with a little dilute hydrochloric acid (1 : 10) in order to remove any particles of zinc that may have got mixed up with it. A greater return will be obtained if one, undeterred by the horrible smell, add some solution of liver of sulphur or ammonia sulphide to the contents of the cask, a black precipitate of sulphide of silver being produced. This is allowed to settle, is collected, and washed as soon as the baths become ferruginous with dilute (1 : 10) hydrochloric acid; then washed with water and afterwards melted. The drawback to this process is that the sulphide of silver has to be smelted. Smaller quantities of fixing baths and residues may be heated with old ferrous oxalate developers; these reduce the silver compounds and give the silver as metallic silver at once, which may, though, of course, only after careful washing, be dissolved in nitric acid."

According to the *Moniteur* a photographic studio has been erected at the top of the National Library at Paris. When an artist or a workman wishes to have a copy of a manuscript, miniature, scroll, or map which is in the library he has to put himself in communication with a photographer, who makes an application in writing to the superintendent for permission to make the copy, and receives in return a card with a number indicating when his turn will come. When it arrives he repairs to the library with his apparatus and chemicals, and there, in presence of one of the library attendants, the copy is made. The Ministry of War and of Marine at Paris have also public studios, and the Museum of Decorative Art is having one built. The *Moniteur* would like to see similar studios erected at the Louvre, the Luxembourg, and the Ecole des Beaux Arts. The *Photographische Mittheilungen*, in commenting on the foregoing, regrets that there is no such provision made for spreading a knowledge of the treasures of the Berlin Museum, and says that though, when the Berlin Industrial Museum was founded in 1867, a studio formed part of the plan, yet there is not one in the luxurious new building. Is there any such glass house for the use of the public in connection with the British Museum and South Kensington? Or is this but one more thing that they manage better in France?

In the *Moniteur de la Photographie* M. Léon Vidal calls attention to the interest offered by the special investigation of the activity and properties of light at great depths of the ocean, and says he has constructed an apparatus for measuring the actinism at all depths, as well as a photographic apparatus intended for photographing the floor of the ocean, by which a true picture of the floor may be obtained, to take the place of the imaginative ones that have so long done duty. *Apropos* of the same subject, M. Milne-Edwards, Jun., says:—"It has usually been assumed that colour is inseparable from light, and that creatures which never see the sun are either of a dark or bleached and indistinct colour. This assumption did not, however, always prove correct, since the darkest parts of the ocean were found to be inhabited by animals in which the brightest tints of red, rose-colour, purple, violet, and blue were richly displayed. Most of the animals of the shrimp species which abound in the deep seas are a bright carmine red. The gigantic holothuria have the appearance of amethysts, and the large starfish are more beautiful than those we find upon our coasts. Their elegance of form and bright yellow reflections are truly wonderful." The question of the influence of light, it seems to M. Vidal, is only casually treated in these remarks, and that not in a very strictly scientific way, since these richly-coloured plants and animals were not examined until they were actually drawn up into daylight; and hence one does not necessarily know what their appearance may be in the depths where they live, since no one has ever penetrated to these depths. Heat, air, and certain gases are found everywhere, but at present one cannot determine how far down the visible and invisible rays of light can penetrate. It is just as unreasonable, he (M. Vidal) thinks, to consider that that decides the question of the effect of light upon colour as it is to make up one's mind that the moon certainly is uninhabited, because neither atmosphere nor aqueous vapours have been observed around it. Such an assumption contains the germ of error in so far as it assumes that it is impossible for living creatures to exist in any part of the universe except under the conditions assigned to plants and animals on this earth.

THE CONVENTION OF PHOTOGRAPHERS IN AMERICA.

The following are abstracts of the President's and Mr. J. F. Ryder's addresses, which had not come to hand when we went to press last week.

The President's Address.

After a few preliminary remarks upon the position of the Association, the progress made since the last convention, and the present status of photographers Mr. J. H. Kent proceeded to say:—

There is one matter of vital importance to every photographer which I regret the necessity of alluding to at this time—a matter that concerns the welfare of all more intimately than anything else connected with photography; I refer to the subject of prices. It is lamentable that there are those in our profession who, by necessity or greed, feel compelled to put a price on their own productions that will barely pay for material and labour employed. Unfortunately, too, the evil is not confined to those commonly denominated "Cheap Johns." If such were the case, and cheap prices always meant cheap pictures, photographers of ability could well afford to pay no attention to this troublesome matter. In some localities this is doubtless the case; but many of us have reason to know and regret that work of an excellent, if not superior, quality is made at prices which these men are pleased to say "defies competition!" This fact, that good work made by men of considerable ability is sold at such ruinous prices, is the source and sum of all the price troubles.

Cheap pictures, as such, are not by any means an unmitigated evil, if, indeed, they are not an actual benefit to the better class of photographers; and really, too, such productions are a necessity with the masses who would be deprived of these luxuries if compelled to pay extravagant prices. The necessity is that there should be a correspondence between price and quality, and the effort of this or any society should be to promote that equality rather than to stimulate strife and bitterness among those engaged in the business.

We cannot, if we would, ignore the fact that photographers, and even those who do not think exactly as we do, have rights that we are bound to recognise and respect.

It should be remembered, too, that, since they are possessed of such rights, we are, and will continue to be, powerless to coerce them into our way of thinking and acting.

It is indeed a matter for serious consideration, and I fear no satisfactory solution of the difficulty will be reached in the near future. Certainly I have no scheme or suggestion to offer other than what I have already intimated that a conciliatory course in opposition to such measures as I have latterly seen advocated by some of our photographic publications should be pursued. We may organise into societies and committees, and legislate low prices out of existence on paper; but the evil will still be as prevalent as ever, while the perpetrators of such will smile at our futile efforts to regulate their business and establish their prices.

What action, if any, this Society should take is for others who may possibly have clearer ideas than your President to suggest or advocate.

It is apparent to my mind that while there is no subject of equal importance there is none more difficult to compass. At anyrate no one likes to be driven. Men are more easily won by argument and appeal to their convictions of right and justice, or, at least, to what would appear to be their own interest, than they are to be forced into compliance with the views of others.

It is hardly necessary that anything should be said at this time relative to the subject of gelatine plates—not that the subject has lost any of its importance or interest to practical photographers, or that it is so familiar to all workers that nothing new can be said or suggested; on the contrary, it appears to me that there is no subject attracting more attention at present than that of dry plates.

While we have learned much of the advantages of this process, we are still far from having discovered all its possibilities. There are those who are still reluctant to concede its superiority over the wet process, many still contending that the crispness and vigour of the old method are not attainable with the new. It is noticeable, however, that most of those entertaining this view are the ones least familiar with the process; and it is doubtful if any who have adopted the dry plate and become familiar with it have ever given up its use and returned to the old bath and collodion.

Its advantages are so many that its abandonment would be such a long step backward that no photographer would think of taking it. In spite of all opposition it is evident the gelatine process has come to stay—at least until something possessing better advantages takes its place.

But, having promised that our proceedings should be characterised by brevity and despatch, I shall not now proceed to violate that agreement by keeping you longer than to express the hope that every member of this body will be actuated by a desire to do all in his power to promote the welfare of the national association, realising that in doing so he is working for his own interest and the interests of his fellow-workers.

On the second day of the Convention Mr. J. F. Ryder delivered an address *On the Business Management of Photography.* He said, after a few apologetic remarks :—

The first necessary requirement—the foundation stone—is a thorough knowledge of every department of the work. An intelligent understanding of one's business is solid capital. The more of that element a man carries the greater is his strength. As we have no established system of apprenticeship, no regular course of study or practice of our young art, the learner is dependent upon a haphazard chance; his aptness at catching an idea, with a natural handiness in taking to new work, and a taste for art even in a small way, prove his good friends in grasping photography.

Considering the many intricate points in chemical requirements, the judgment necessary to be exercised at every stage of the work, the many handlings and processes which depend one upon another, and all necessary to the proper production of a finished photograph, it is really a matter of surprise how successfully it is accomplished with the small chances the workman has for acquiring knowledge. I say this, believing the instances where photographers are really educated in the art-science of the profession they claim to be masters of are very few. I hope the time is near when regular schools of photography will be established and sustained in this country, where the learner may have the benefit of good teaching under competent professors, where study shall be necessary, so that he should be compelled to pass a rigid examination in chemistry, optics, physics, light, lighting, composition, and drawing, before he should be entitled to a diploma which shall be his voucher for competency.

Then we could expect intelligent skill in our *employés*, and the public could feel assured they were being served in a proper manner.

The coloured servant of a surgeon, explaining why his master charged twenty-five dollars for the performance of an operation in surgery which took but ten minutes to do, said he charged five dollars for the work and twenty dollars for the know how.

To fit ourselves in the best way for the pursuit of our art, which is becoming yearly more an art and more closely allied to science, buy books, subscribe for journals, magazines, and papers upon the subject. Make your collection of photographic literature a special library, and then make its acquaintance—the more intimate the better. In this way you become master of the requirements of your business, which is a rock-bottom foundation upon which you may build with all confidence and security.

Make a collection of studies, and encourage yourself and your operator to frequent examination of them.

I have large specimen books, the leaves of which are of tar-board 22 × 28 inches. To these tar-boards on both sides I glue mounted photographs, the best examples of work I can find. I purchase and I exchange; I have the work of friends and of strangers. It is a valuable collection for reference. They are kept where my operator has constant access to them; from them he can find almost every style of lighting and posing, as well as the peculiarities of many noted operators.

Next in value to superior quality in your productions is a safe and careful system in all the various departments—from writing an order for a sitting to delivering the finished picture into the hands of your customer. Such system should be observed; the soul of that system should be order and cleanliness.

The man who satisfies his conscience that he cannot afford to spend money in thoroughly renovating as often as once a year, and refurnishing when needful, is a poor manager and works against his own interest. Nothing commands more prompt respect than tidiness. A seeming of prosperity soon brings the reality. People like to patronise a prosperous man, and naturally avoid a poor or an unfortunate one. All that shows an air of thrift and systematic order should be practised and enforced.

Keep your show of specimen pictures fresh by frequent changes. Your customers will visit you oftener if you have new attractions. They will take pride in you, and make your establishment one of the places to be visited by strangers and their visiting friends, among whom you will find good customers.

How to treat with customers.—Here comes the place for exercise of judgment—for real generalship. To be polite, attentive, genial, and at the same time firm in adhering to safe rules for your own protection, is a difficult thing to do; yet it can be done. A correct start often saves misunderstandings, which are to be avoided by all means. It is a great mistake to have serious differences with your patrons; you must remember that great consideration is due to your sitter. Perhaps you sometimes sit yourself and find you are whimsical and exacting; you like to try again, for some reason you cannot quite explain. Perhaps when you go to your tailor you are not at once suited with the fit or hang of your coat; his telling you it is all right does not quite convince. Remember these things and be patient; you can make another sitting as quickly as you can make an argument. The sitting would perhaps convince them; your argument would not. Make your prices sufficiently high to justify the use of a number of plates and a half hour's time if necessary. You can afford this occasionally. If the exactions of your sitter be too great you are entitled to charge for extra service. State it pleasantly but firmly; sugar-coat your words where the subject is disagreeable.

In bargaining, or arranging the details for a sitting, have everything clear and distinctly understood. If additional styles beyond what is described in your order are asked for, then is the time to mention the additional price and to stand by it.

I believe it entirely fair to make for all sitters two good negatives, differing in position, so that they may have a choice. If they desire more plates used it is very proper they be required to pay extra for them, particularly should sitters be made to understand a change of dress or toilette means an extra charge for new sittings.

Do not be too obsequious to your aristocratic customers and domineering with those of modest means, who are generally sensitive. Be polite to all. Remember where you get one dollar from the capitalist you get ten from the middle class—the working people. Be prompt as possible in finishing and delivering your work; make no promises on that point except you are sure of keeping them. Impress your customers with the fact that your word is to be relied upon.

Never put off the securing of an order for another time; clinch it on the spot. It is never too late in the day to make a sitting—that is, to take a man's order for a sitting. Many a time have I written orders for sittings by gaslight, and given my client into the hands of the operator. With his money in the till he is sure to come for his proof in the morning, and be well satisfied to try again on learning last night's effort was not entirely a success. Had I told him it was too late in the day, and advised his coming again, I should probably not have seen him more. With a desire for sitting while his mind was upon it he would probably try my next-door neighbour, who, with more enterprise than I had shown, would gobble him.

The time to take money is before the sitter goes into the operating room —particularly should this apply to strangers and parties regarded doubtful. All photographers who fail in this important rule are practising an injustice upon themselves. Prices for photographs have become greatly demoralised. Many of our prominent and good men have been led or driven—I might say "clubbed"—into this great wrong. I will venture to assert that four in every five who have fallen into low prices are ashamed of it, and would be glad to get back to more respectable figures and a more respectable standing among their fellows. Low prices are in every way degrading, the work is carelessly made, the standard of excellence is lowered —in fact, is lost; ambition sinks to indifference, enthusiasm is killed. The work becomes drudgery—devoid of interest or pleasure.

Is there a remedy? Let us see. In all places where photography is practised are men and women who want the best that can be made, and will pay good prices for what they believe to be superior work. It is possible for photographers to invest their business with a tone and dignity that will be recognised by the people. There are many prominent instances to prove my assertion. This good city of Cincinnati stands at the front as an example to all other cities and to all other photographers of this country. The gentlemen who practice photography here are not devising schemes for decorating the fences with the skins of their neighbours. They are so wise as to be on the best terms with each other, both in a business and a social sense. They are quite willing that each other should live and thrive. They are prosperous; they are honoured.

The curse of our business is this curse of low prices. There is no good reason for it. There is no wisdom or advantage in it. It is a wrong to yourself, your neighbour, and the art you should be proud of, and which you should feel bound to protect.

Reform must come. I heard when a child that the city of Rotterdam, in Holland, was the cleanest city in the world, and the way it came about was from everyone scrubbing their own doorstep. I have always remembered it. My friends, the way to bring about reform in the abuse we are talking of is not to wait for your neighbour, but to commence scrubbing your own doorstone.

Put your establishment in proper train for an advance to a higher grade of work and a higher scale of prices. The public, recognising your progress, will follow you; if your neighbour will follow you also so much the better for you both. If he will not, you have, by your act, proved yourself his superior, and will hold the advanced ground you have taken. Elevate your art and it will elevate you. Make your prices high, and make your work worth all you charge for it.

This, gentlemen, is the road to success. Look about you and prove its truthfulness. The men who have been fortunate in our business have been faithful to the course I have laid down.

RECENT PATENTS.

APPLICATIONS FOR PATENTS.

No. 11,556.—"Method of and Apparatus for Taking Photographs by Artificial Light." (Complete specification.) E. Himly, 28, Southampton-buildings, London.—*Dated August* 22, 1884.

No. 11,623.—"Photographic Albums." J. Tirebuck.—*Dated August* 26, 1884.

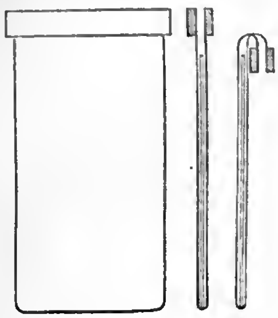
Changing Sensitised Plates in Photographic Cameras.

Patent specification. By James Sturrock, Dundee.

The first part of my invention relates to cameras of the ordinary well-known kind, in which pictures are obtained by exposure in the camera of glass plates properly sensitised. It has for its object a novel method of constructing such cameras or slides for cameras, so that the sensitised plates can be more readily changed when required. I make at the back of the camera a space to hold a sensitised plate. This space is open above, and is provided with a flange, or other similar device, to which can be readily attached by an elastic band, or other convenient means, the open mouth of a bag made of paper, cloth, india-rubber, or other suitable material impervious to light; or it may be made of tin, cardboard, or other rigid substance, with a flexible neck or mouth of rubber or cloth suitable for attachment to the camera. I fill the bag in a dark place with a sensitised plate, and then close or fold the mouth to exclude the light and secure it by a spring, clip, elastic band, gum, or other equivalents; and having fixed its mouth to the camera, as already described, I remove or undo the fastening, invert the bag, and deposit the sensitised plate in the camera. After exposure the plate is again slipped from the camera into the bag, and the fastenings again put on, and the bag with the plate removed from the camera, when another bag containing a plate can be attached. The plates can be stored away in the bags, both before and after exposure.

In the second part I make a separate holder or slide, having a space to hold one or two sensitised plates, as in the ordinary dark slides, but having a flange, or other similar device, to which the bag can be attached, and a plate or plates put in, as already described, and which can be inserted in the back of the camera in the usual way.

FIG. 1. FIG 2. FIG. 3.



In the accompanying drawings *Fig.* 1 shows front view of bag. *Fig.* 2 shows section of bag. *Fig.* 3 shows bag folded so as to exclude the light. *Fig.* 4 (which, with 5 and 6, we have not engraved) shows bag attached to slide or camera. *Fig.* 5 shows bag raised ready for plate to drop into camera or slide below. *Fig.* 6 shows section of paper bag folded.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is:—

First. The arrangement in cameras or slides for cameras for enabling flexible bags to be attached substantially as described.

Second. Flexible bags for conveying plates to or from the camera or slide, made so as to fold or close at the mouth, and secured by a spring, clip, elastic band, gum, or their equivalents.

Third. Bags, by means of which sensitised plates can be placed into, or taken from, the camera, or slide, without introducing the hand or other agency into the inside of the bag.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

At the technical meeting of this Society, held on Tuesday last, the 26th inst., the chair was occupied by Mr. W. England.

Mr. A. Cowan showed an appliance for adaptation as a camera front to regulate the sizes of stops for lenses of different foci, so that they should work at a given speed. A description of this appliance will be found on page 508 of the present volume of The British Journal of Photography, in the report of the proceedings of the London and Provincial Photographic Association.

Mr. W. E. Debenham proposed, as a subject for investigation and discussion, the effect of different exposures, with development to suit, upon the quality of the resulting image. At a previous meeting Mr. Léon Warnerke had shown some photographs of the interior of the palace of Moscow, the work of Baron Kossuth. These photographs were remarkably fine in quality, possessing in a striking degree the characteristics which were generally spoken of as particularly belonging to wet plates. It was mentioned that the negatives, upon developing the first plate, were found to be much over-exposed—perhaps six times—and that the plates exhibited had, therefore, been immersed in a bromide solution before development to overcome this defect. They were informed that the plates had been very rapid ones, and the question arose—"Whether the result would have been as good as if the exposure had been such as to be adapted to the ordinary development." The points that he proposed for discussion would be two:—First, what is the treatment which will give the finest result upon a gelatino-bromide plate, independent of rapidity of exposure? and, second, if it should be found that treatment requiring a longer exposure gave a better result, what should be considered as the proper or normal exposure?

Mr. T. Bolas said that Mr. Debenham had put into a definite form ideas which had been hanging about for some time. With wet collodion a certain result was obtained when copying by giving a long exposure and slow development, and probably considerable advantage would accrue from a thorough investigation of the subject as applied to dry plates.

Mr. W. M. Ashman observed that the differences of make of plates would also have to be taken into account.

Mr. Cowan thought that the best result was to be obtained by a full exposure and restrained development.

The Chairman, for landscape work generally, preferred slow development and a good exposure. For a normal developer he used about a grain to each of the constituents—pyro., bromide, and ammonia—to the ounce of water. He also liked the addition of a little sulphite of soda, although it somewhat slowed development.

Mr. Ashman remarked that it was surprising what a quantity of ammonia might be added without injury—provided that but little was used at first, after the image had come up—and what an amount of density could be thus obtained.

Mr. Debenham hoped that definite and precise experiments would be made, and the subject be continued until definite results were settled.

Mr. Ashman proposed to the members to try experiments with reference to Dr. Vogel's method of obtaining true representation of coloured objects by the use of stained films. He himself had experimented in that direction, using tincture of turmeric and some obtained from the flower of the marigold.

Mr. Debenham inquired whether the results of Mr. Ashman's experiments had been to confirm Dr. Vogel's view as to optical sensitisers.

Mr. Ashman replied that they had. He found that the sensibility to blue rays was diminished, and that to yellow and brown colours increased, by staining the plate. He had not added the tincture to the emulsion, but poured it on to dried plates. He had for convenience generally exposed whilst still wet with the tincture. He found no advantage from adding ammonia to the tincture.

Mr. Cowan inquired whether the tincture was used of strength sufficient to make the plate perceptibly yellow.

Mr. Ashman replied that it was.

Mr. Debenham remarked that the somewhat greater sensitiveness to yellow rays of a plate containing iodide in addition to bromide which had been observed recently by Dr. Eder, and many years since by Herschel, might be due to the yellow colour which iodide of silver imparted.

Mr. Bolas remarked that Dr. Löbse, of Potsdam, had recommended the use of turmeric. It was easy to procure, whilst pure eosine was not.

Mr. Arnold Spiller said that it was safer to experiment with turmeric than eosine, as Dr. Vogel had stated that commercial eosine was useless.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on the 21st instant, the chair wa taken by Mr. T. Waltenberg.

A letter from Mr. F. H. Davies, of the American journal *Photography*, with reference to having early reports of papers read at the Society's meetings, was read, and the Secretary was directed to reply thereto.

A question from the box was read—"Where can silver or electro-silver wire gauze, of suitable size for dividing set emulsion, be obtained?"

Mr. J. Barker had for some time been endeavouring to obtain the article for his own use in emulsion making, but without success.

Mr. W. E. Debenham had had similar experience some two or three years ago. A well-known firm of chemical apparatus manufacturers had said they would get it made, naming a certain price. After several calls they informed him that it would cost considerably more—perhaps four or five times the sum first mentioned—and finally said that they could not supply it at all.

Mr. A. Cowan said that he would advise anyone requiring it to make it or a substitute for it himself by driving in pins round the margin of a wooden tube, and then taking the wire across from these pins from the opening, first in one direction and then across. It would not matter that the wires merely crossed instead of being woven. For his own part he found the material known as mosquito netting, which could be obtained at the large drapery houses, quite satisfactory.

Mr. A. Haddon inquired whether it was necessary to silver the wire used.

Mr. W. M. Ashman said that it was not, and that copper wire would not injure the emulsion during the short time it would be in contact with it.

Mr. Cowan suggested that copper gauze should be dipped in melted tin and so coated with that metal, which was quite harmless.

Mr. W. Cobb used a netted material made of fine whipcord.

Mr. Barker thought that during the hot weather it was better to use a mechanical dividing appliance than to squeeze through any cloth fabric with the hands.

Mr. Haddon used a brass tube and plunger as a syringe, and on the end of this was fitted a brass plate which was pierced with holes as closely as they could safely be placed. Each piece of brasswork was electro-silvered.

Mr. Cowan observed that Mr. Bedford, having high pressure of water from the main, used that instead of a plunger to force the emulsion through the division.

Mr. Ashman spoke highly of the use of sulphite of soda after mercury for intensifying negatives. Common washing soda being used the mercury did not produce the desired alteration of colour, but if sulphurous acid were added, then darkening commenced at once. He (Mr. Ashman) then referred to some experiments he had made by staining gelatine plates with tincture of turmeric in order to alter their colour sensitiveness and cause them to give truer representations of coloured objects. This was a method of proceeding which could be tried by all, and was not limited to those who made emulsion themselves. He found that the sensitiveness to blue was lowered and that of the colours near the other end of the spectrum was considerably exalted. The general sensitiveness of the plate was diminished by about one-half.

MANCHESTER PHOTOGRAPHIC SOCIETY.

On Saturday last, the 23rd inst., the above Society held its tenth outdoor meeting for this season. The place chosen, though near Manchester, was quite new to those who went, and amply repaid the little extra walk, even on a hot afternoon.

Under the leadership of Messrs. Charles Pearson, Jun., and Thomas Chilton the party left the Central Station at 12.43, and quickly reaching Peel Causeway found carriages waiting to convey them to Oversley Ford, on the river Bollin—a further distance of five miles. Here the road and the carriages were left, and a delightful meadow path taken by the river side following the stream. The afternoon was almost perfection for photography, so that cameras were soon unpacked and at work on various river, meadow, and cattle scenes.

A singularly-picturesque timbered and ivy-covered cottage a little way out of the valley was the next object of attraction. The battery of cameras and lenses brought to bear upon it at one time was something startling, giving the impression to the natives that the old place was undergoing a state of siege. Various other woodland and river scenes were found on proceeding further down the valley.

The very hot afternoon made it thirsty work carrying the various heavy packages necessary, so that a visit to a large model farm, where a quantity of delicious new milk was obtainable, was very much appreciated. One of the "drier" members who had gone on in front announced that he had discovered the "milky way!"

At Castle Mills some few more plates were exposed, and the journey continued down the valley to the first footbridge, where the river was crossed, the valley left, and the road taken direct for Ashley, as there was no time for any more work.

Tea was provided at the "Greyhound," Ashley. Messrs. Smith and Chilton took groups of the members, and while the exposures—which were somewhat long—were being made, the train could be heard coming, causing some of the "sitters" to have a rather impatient and anxious appearance. A rush for the inn, a scramble for the instruments, a dash to the station, and a race along the train concluded the day's work. Manchester was reached at 7.30 p.m.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

This Association met on Friday, the 4th ult.,—Professor Vogel in the chair.

Two new members having been admitted, a couple of photogravures, sent by Herr Obernetter, were examined. They were produced from negatives taken from nature (the subject of one was an Arab in a yellow turban and red jacket—the other was an animal piece), upon Obernetter emulsion, treated with azaline, by Vogel's method. The results were considered very good, and a copy of a colour scale taken by the same gentleman upon an azaline plate, without the interposition of a yellow glass, was considered perfectly successful in its representation of the value of the tints.

The Chairman called attention to the great advantage of using azaline plates for interiors.

Herr Schmid, engineer in the Imperial Navy, spoke of the views of the outlines of the coast and headlands taken by him from the deck of a gunboat [see Professor Vogel's article, page 502 *ante*], and showed a number of the pictures so obtained.

Herr Quidde inquired whether the weight which balanced the camera did not swing a great deal sometimes during the voyage, and so prevent or disturb the exposure.

Herr Schmid said that was so, and when not actually in use he had to disconnect the weight; otherwise its increasing momentum would have injured the apparatus. He also disclaimed any personal merit in the excellence of the pictures, attributing it all to Professor Vogel, who designed the apparatus, and Herr Sachs, who prepared the plates.

Herr Haberlandt reported concerning his experiments with the blue intensifier, expressing himself very favourably regarding it.

Herr Moll sent a sample of a mountant, called "alligin," said to be suitable for mounting photographs, keeping well, and being free from lumps.

Herr Schultz-Hencke, who had tried it, praised it highly, and said that, in spite of the long distance it had come (from Vienna) and the present heat, there was no trace of acid in it.

Herr Quidde read the programme of the thirteenth wandering meeting of the German Photographic Society, which is to be held at Berlin towards the end of August, and in connection with which an exhibition is to be organised. The price of tickets to the festival for members of the German Photographic Society is ten marks, and for non-members thirteen marks.

The contents of the question-box having been dealt with, the advisability of having the usual summer recess was discussed, when it was resolved by a majority to have the next meeting on Friday, 19th September, though a considerable minority would fain have had the meetings regularly continued all the year round. It was also resolved that on the first and third Fridays of each month, when if it were not for the holidays the Society would meet, any members who might feel inclined might have an informal meeting in the Leipziger Garden, No. 132, Leipzig-street.

Correspondence.

EDWARDS'S MACHINE FOR COATING PLATES.

To the Editors.

Gentlemen,—In your current number appears a sketch and description of a patented machine for coating plates with emulsion by Mr. B. J. Edwards. On reading and examining the description I find Mr. Edwards has not sufficiently informed himself of what mechanical appliances similar to the one described are, and have been for years, in use for manufacturing purposes.

The principal feature in the machine is the adoption, as the means of supply, of the coating roller and emulsion trough as described some years since in this Journal; but from the roller the emulsion is removed by a scraper, and conducted down an incline to where it meets the plates, being drawn on an endless band below to receive it. This "movable and adjustable scraper" is claimed as an essential part of the patent. Let us then see whether it has hitherto been known or used. Had Mr. Edwards made sufficient inquiries he would have found it in use as under:—

a. In the manufacture of pigments, in which rollers revolving in a trough carry the supply forward to where it is received by "movable and adjustable scrapers," and thence in some cases spread on plates for desiccation, in others collected, and repeatedly passed through.

b. In the manufacture of floor cloths, and other floor coverings, where the canvas is drawn under the scrapers identically with Mr. Edwards's description, while pigmented fluid is conducted on the moving surface by the roller and "movable and adjustable scrapers."

c. In the manufacture on a large scale of plasters for medical uses, where endless strips of muslin are drawn, precisely as Mr. Edwards does, under the stream of liquefied balsamic preparation, with the trough scrapers, &c.

d. For applying to paper various adhesive and colouring materials. Postage and other stamps are thus gummed in endless bands, waterproof material applied to brown paper for packing purposes, and tints applied to papers for decorative purposes.

It will be seen by these instances—which are but a few—that the "movable and adjustable scraper" is well known and in constant manufacturing use.

The cooling chamber must be dealt with in the same way. During the last few years few subjects have made greater progress than the study of artificial lowering of temperature to preserve organic materials or carry on chemical or mechanical processes impossible in a high temperature. This cooling, as applied to gelatine plates, is perfectly known. In America it is found in every dry-plate works—indeed, is the most important department.

The endless band is one of the best-known items in mechanical science, and is to be seen in most factories. It seems inconceivable that because it was found the friction scraped off superfluous emulsion at the back a patent should be maintained.

It will be seen from the above that all essential parts of this machine are in use for various purposes, and have long been so.—I am, yours, &c.,

Kingston-on-Thames, August 26, 1884. Samuel Fry.

INSTANTANEOUS SHUTTERS.

To the Editors.

Gentlemen,—With reference to the article on *The Use of Instantaneous Shutters*, which appeared in your issue of the 22nd instant: I purchased one of Cadett's new drop shutters with patent pneumatic ball and tube last May, and find it most efficient for ordinary work, but for instantaneous subjects it is useless. For instance: in taking cattle whose tails are in rapid movement the animals come out clearly, but their tails are fan-shaped. Again: in taking persons playing tennis, the one scoring appears double, and the arm of the one taking the score is not seen. The shutter is very light and beautifully made, and if it could be constructed to act with greater velocity it would be perfect. I agree with you that the foreground may take care of itself, for I have generally found that if I attempt to give the foreground more exposure than the sky an unnaturally-lighted picture results.

What we really require is a *drop* shutter acting with great rapidity—far more so than gravity can give—capable of some adjustment as to that rapidity, working with full aperture, and falling so smoothly as not to cause any vibration to the camera. Do you know of any shutter which fulfils these conditions?

I understand that the Phœnix does so; but, as there appears to be a double-flap action of some kind, I doubt its power of being able to take a game of tennis or any movements equally rapid.—I am, yours, &c.,

August 26, 1884. A. A. Mantell, M.D.

TOURISTS' CAMERAS.

To the Editors.

Gentlemen,—In relation to the interesting article by Mr. A. Pringle in your last, may I ask Mr. J. Traill Taylor whether his experience with removable dark shutters to slides, with a cut-off, is the same as that of Mr. Pringle, or whether the latter was using an imperfect specimen? As it is to be hoped that some manufacturer or other will soon try to do something to remove long-standing grievances in connection with the construction of tourists' cameras, he had better not be presented with conflicting evidence in this correspondence as to what is really good.

I did not say my apparatus took ten minutes to fix, but that it took ten minutes in all—(1) to take it from its case; (2) to fix it; (3) to unfix it; (4) to pack it away again. It should be ready for use inside its case, with the power of fixing the case on the stand.—I am, yours, &c.,

August 23, 1884. W. H. Harrison.

THE ETHOXO LIGHT.

To the Editors.

Gentlemen,—In reply to Mr. W. Broughton's letter, in your issue of Aug. 1st, let me say I have taken particular pains to disclaim priority in the use of ether for producing the lime light, both in the circulars which I have issued and in communications to periodicals; nor have I, as Mr. Broughton would have it inferred, obtained a patent in this country for anything which he had already published in England. What I have claimed, and what belongs to me by right of invention and prior publication, is the "saturator" *with porous filling*, which, as constructed by me, was the first to produce a reliable and perfectly-steady light with ether, and which remains today, so far as I can learn, the only form of ether apparatus which really fulfils all the requirements, and is calculated to give general satisfaction.

If Mr. Broughton did, as he now claims, first use a saturator with porous filling, he forfeited his right to any credit in connection therewith by neither publishing the fact at the time nor making a success of it. As for the rest, it is useless to deny the superiority of my apparatus so long as it it is preferred to any other where it is known, and has a good sale at a price which would cover the cost of half-a-dozen of the original Broughton ether chambers, which everyone has a right to make and use. The fact is, porous saturators have not yet become popular in England simply and solely because they have not been properly constructed, and have faults which those of my make have not.

Mr. Broughton's pumice chambers are undoubtedly useful with his apparatus, but are quite unnecessary with my own, which is absolutely safe against a dangerous explosion—has been proved conclusively to be so—and will never even "pop" in the jet if managed according to instructions with such jets as are recommended.—I am, yours, &c.,

Philadelphia, U.S.A., August 15, 1884. FRED. E. IVES.

THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN: ITS REPORTS AND THE PHOTOGRAPHIC PRESS.

To the EDITORS.

GENTLEMEN,—Mr. Herbert B. Berkeley, in your issue of the 22nd inst., at last admits that I have not misrepresented him: but if his present statement—that he had not accused me of misrepresentation—were correct, I should not have actually done so in complaining of a charge which he says was never made.

Mr. Berkeley now says that "the charge of misrepresentation against Mr. Debenham existed in his own imagination merely," and his statement that he "refused to withdraw the term as applied to the Editors and anonymous writers" implies that it was only intended to be applied to them. In the letter (July 11th) of which I complained, Mr. Berkeley, after devoting some space to me, says "this also in answer to Mr. Pringle," and goes on—"The gentleman just mentioned is not the only one who has misrepresented, or misread, my letter," and afterwards proceeds to discuss Mr. Pringle's letter. The "gentleman just mentioned" would, perhaps, grammatically mean Mr. Pringle, but logically it must refer to the writer whose views have been discussed, namely, myself.

Further on Mr. Berkeley said—"Like the other writers, the Editors totally misrepresent my meaning." He now says that he did not charge me with misrepresentation, because he did not say "*all* the other writers." Logically and grammatically the phrase, "the other writers," without limitation, includes "all," whether anonymous or otherwise.

In Mr. Berkeley's letter of July 25th he did not withdraw the charge of misrepresentation against me, but stated that he had not made it: at the same time his question, "If a man writes that which is not the case, does he not misrepresent?" implied that he might well have done so. Now, a denial of having made an accusation is not the same thing as suitably withdrawing it. Other writers—gentlemen whose names are honoured by your readers for their contributions to your pages—have not hesitated, when the circumstances have been much less aggravating, to offer an apology which which has been heartily accepted. Such incidents then, like the *amantium irae*, lead to the increase of good feeling. Mr. Berkeley prefers another method; but I think it is really too much for him to complain, as he does, that the matter has degenerated, by no initiation of his own, into a personal contest.—I am, yours, &c., W. E. DEBENHAM.

August 26, 1884.

[So far as the charge of misrepresentation concerns ourselves: after reading Mr. Berkeley's elaborate explanation, we see no reason to alter our reading of his original remarks. The subject has been sufficiently ventilated, and the correspondence must now close.—EDS.]

Notes and Queries.

"Is there any patent obstruction in the way of my employing the electric light for portraiture?—G. B. BROWN."——We reply: Our correspondent may employ without hindrance any artificial light he prefers.

X. Y. Z. asks—"How shall I stain the inside of a box black without having recourse to varnish?"——We reply: Let him brush it over with an infusion of nut-galls and logwood, and when dry again brush it over in the same way with a solution of sulphate of iron. If the blueness of the colour be objectionable allow the surface to become dry, and then oil it with a mixture of one part of linseed oil to two parts of turpentine.

A PROFESSIONAL PHOTOGRAPHER complains very strongly of his lens having become much slower in working than it was when he first purchased it five years ago. He is desirous of knowing the cause of such slowness.——We reply that if he make the lenses quite clean and lays them down upon a sheet of white paper he will see at a glance whether, or to what extent, they have become discoloured by the tint assumed by the paper when seen through them. If there be no perceptible darkening of the paper, then the increased slowness will exist, in all probability, in the imagination of our correspondent. But if, on the contrary, the glass of which the lens is composed be found to be of a yellow or brownish colour, then discard it at once and obtain another.

GEORGE SUTCLIFFE wishes information as to the best way by which to prepare albumen for photographic purposes, mainly those connected with dry collodion plates.——We reply that it is rather difficult to indicate this, because in each dry collodion process that has been published the directions given have usually included the beating up of the albumen. For example: in some cases it was beaten to a stiff froth, allowed to liquefy (which occupied several hours), and a small lump of camphor added to preserve it from putrefaction. In other cases ammonia was added in the proportion of ten drops to the ounce, this being followed by frothing as before. A third method, which has received much favour, consists in adding a few drops of glacial acetic acid to the albumen, stirring this up with a glass rod, and allowing it to stand without any beating up or frothing.

A YANKEE inquires if Professor Towler, the author of the *Silver Sunbeam*, is still alive, and whether he continues to take an interest in matters photographic. He (our correspondent) has been connected with photography in the United States for several years, and wishes to know why men like Professor Towler and Mr. M. Carey Lea, if they be still living, are allowed by the fraternity there to remain in the background, when such lustre might be shed upon their barren conventions by the presence of men of such eminence.——In reply: We are happy to say that both of the gentlemen named are still living. We are quite of the opinion of our correspondent as to the desirableness of securing lectures (for such we take to be his meaning) at the meetings of the conventions from men of this class: but whether they would consent to do so, if requested, is another matter.

F. J. O'B. inquires:—"Supposing (which in my case is unfortunately not a matter of supposition, but of actual fact) that a four-inch lens—four inches in diameter I mean—has sustained such a severe contusion at one side of the front lens as to have shivered the glass to the extent of a sixpence, may such a lens ever be rendered good for anything again?"——In reply: Examine the lens very critically to ascertain whether the imagined fracture of the glass may not in reality be one of the balsam by which the component parts of the front lens are cemented together. If this be the case let it be removed from the cell and re-cemented. But if the glass itself be fractured paint the shivered portion over with opaque black varnish, to prevent any of it being seen from behind, and then mount the lens so that the stopped-out portion shall be at one side rather than at the top or bottom. By adopting such an arrangement it is probable that the lens will work no worse than it did before the accident.

"I HAVE a one-eighth inch microscopic object-glass which defines very well when used upon objects that have not got very fine lines. When the light is somewhat oblique it shows the markings upon the *P. Formosum* very plainly, but will not do so upon the *P. Angulatum*. As you will have already guessed, it is of French manufacture and is not by any means pretentious. What I wish to know is whether such an objective will prove of any use in photomicrography, and, if so, what particular class of objects it will be good for.—B. H. A."——In reply: The object-glass referred to will answer for photographing such objects as can be visually examined in a satisfactory manner by its agency. From the description of what it can do it is evidently one of a very narrow angle. Is our correspondent certain that it *is* the power (one-eighth) he alleges it be? It may, more likely, be only a quarter. It is impossible to speak of its capabilities for photography unless it were tried for that purpose. It will probably be slightly over-corrected for colour, which will necessitate one or two preliminary trials when focussing.

A THIEF AT NOON.

I LOITER near the peasant's cot
(And "pot" it with unerring shot),
And at the crows that scamper by
My mute artillery let fly.
The "Lion on the old stone gate,"
Sung by Lord Alfred, meets his fate
With stoic calm; no time to carp,
My shafts are keen and cruelly "sharp."

Nor Hodge, nor haughty Vere de Vere,
The loutish peasant, or the peer—
Howe'er he fume, or curse, or gasp—
When once within my tender clasp,
Can slip his gyves. The lowing kine,
Unconscious prisoners of mine,
Might roar the welkin into rain,
And gnaw their boads—yet gnaw in vain!

I court the light and woo the shade;
With both I toy, as toys a maid
With rustic clown. I pet and coax,
And flout and scorn, and chide and hoax,
And goad them both. And all my prey
I slaughter in the glare of day.
I cloak them whilst there's light about,
And with the night I force them out.

No poacher half so deft as I,
No burglar so demurely sly;
I "bag" a tree or "grass" a roe,
And not the ghost of trouble know;
Your mediæval robbers pale
Beside the deeds that dog my trail.
I've nearly caught the sun at noon,
And t'other night secured the moon!

The burglar fears the light of stars,
The poacher's wanderings Luna mars;
Their boldness only blooms at eve—
I carry mine upon my sleeve.
"Light! give me light!" no night-bird I,
Who steals with sunbeams in his eye!
I'll drag a planet into sight,
Or take the D——l, if there's light!

I kill with speed, but always stop
To give a short and hasty drop;
And with a neat decapitation
I often couple amputation.
The twinkling of the visual orb
Will of itself more time absorb
Than I should occupy in limnin'
A hundred thousand men and women!

THOMAS BEDDING.

Exchange Column.

No charge is made for inserting these announcements; but in no case do we insert any article merely OFFERED FOR SALE, *that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a* NOM DE PLUME *be thought desirable), otherwise the notice will not appear.*

Wanted ferrotype plates and other wet plate material in exchange for a very rapid *carte* lens.—Address, AMERICAN STUDIO, Queen-street, Exeter.

I will exchange Tench's No. 6 wide-angle plano-lens for Ross's 5 × 4 medium-angle doublet, four-inch focus. — Address, T. JONES, photographer, Ludlow.

I will exchange a *carte* lens, with rack and pinion, for a drying oven, platinum crucible; or offers.—Address, HERBERT GOVER, 101, Waterloo-street, Hanley.

I will exchange a lot of gelatino-bromide pictures, both painted and black and white, for anything useful in photography.—Address, C. T., 36, Orbel-street, Battersea Park, S.W.

I will exchange a quarter-plate *Le Meritoire* complete, value thirty shillings, with extra double slide. Wanted, a half-plate folding camera with one or two slides; difference adjusted.—Address, 9, Mayo-road, Brighton.

I will exchange a good half-plate lens, combination, for views or portraits, cap and flange, Waterhouse's stops, English makers, for a whole-plate camera, dark slide, folding tripod; difference adjusted.—Address, H. Y., Edinburgh Post Office.

I will exchange my fifty-two-inch Coventry-made bicycle roadster, in fair condition, for good camera and lens. Want a 10 × 8 or 12 × 10 camera complete for studio; photo. of machine, two stamps.—Address, PHOTOGRAPHER, South-street, Romford, Essex.

I will exchange an interior background, conservatory background (new), cabinet burnisher (new), Lancaster's camera, press, head-rest, side-slip landscape, and posing-chair (the property of a photographer going abroad), for anything, except photographic materials.—Address, J. WARD, 8, St. Walburge-street, Preston.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

NOTICE.—*Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a* NOM DE PLUME *as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.*

PHOTOGRAPHS REGISTERED.—

Joseph Stephen Brown.—*Group Photograph of Clergy and School Teachers of St. John's, Bridgwater.*

John Owen, Newtown, North Wales.—*Fire Photographs of Wynnstay, the Residence of Sir W. W. Wynn, Bart., M.P., Ruabon, Denbighshire.*

William Pankhurst Marsh, Norfolk Cottage, Bognor.—*Four Instantaneous Photographs of Sanger's Circus Procession, and One of the Elephants and Camels in the Sea at Bognor.*

WITNEY.—We are unable to give you the cost of advertising in the American photographic publications.

WM. C.—If an excess of potash has been used in the preparation of the solution lime will be thrown down, but it will do no harm.

A. B.—The only method by which we could decide the question is by making an analysis. For this, we regret to say, we have not time at present.

W. M. H.—We are unable to say with certainty, but we have an impression they are to be procured from Messrs. Perry and Co., Holborn Viaduct, E.C.

F. B.—1. The only formula published by Mr. Berkeley is four grains of the sulphite to each grain of pyrogallic acid.—2. If that be the golden rule (?) so much the worse for theory.

S. R. B.—We believe the suit is still pending, but when it will come on for hearing is a matter of uncertainty. It cannot until after the long vacation is over. The matter is not, as you surmise, dropped.

E. W.—Without knowing more of the circumstances we should be inclined to attribute the defect to damp. So far as we can judge from the appearance of the image the emulsion would appear to be all right.

A. J. McMAHON.—The emulsion is now quite useless except for the silver it contains. From long keeping during hot weather the gelatine has become decomposed. Do not waste time in trying to "vamp it up," but make fresh.

INQUIRER.—Had this correspondent conformed to our rule, by enclosing his name and address, his four or five queries would have been answered. We never reply to questions unless the correspondent forward his name and address. See heading to this column.

X. X.—1. There is no means of removing the stains; but as you only appear to require the negative for enlarging from they will not matter, as you may avoid them in the transparency.—2. You had better employ the formula supplied with the different makers' plates.

E. BOISSONNAS; F. W. VÉREL AND CO.—Messrs. J. and E. Hall, 23, St. Swithin's-lane, E.C., supply cold air machinery, such as are referred to in our issue for 1st instant. Other firms supply them also, but Messrs. Hall manufacture a smaller apparatus than the others.

W. M.—We should advise you to have some light wooden frames, covered with thin muslin, which can be fitted over the roof portion of the studio during the summer months or when the sun is very brilliant. In the winter, or when the light is dull, these can be removed and the full light utilised.

WHITE ROSE.—The simplest and least expensive instantaneous shutters are those of the "drop-shutter" form. Consult our advertisement columns. There are many different makers, but we cannot undertake to recommend any particular manufacturer. It is against our rule to do so.

A WELSHMAN.—Methylated ether, if good, will do quite well for making collodion for wet-plate work. It should have a specific gravity of ·720 or ·725. If weaker than this it should not be employed. The alcohol will answer perfectly; indeed, for the iodiser it may be slightly weaker than your sample.

CHAS. SPENCE.—The red spots on your prints appear to be caused by bubbles of air adhering to them while in the toning bath, and these have prevented the action of the gold solution. Keep the prints moving all the time they are in the solution, and see they do not get air-bells enclosed between them.

W. W.—It appears to us, from the print forwarded, that the upper portion of the building is more strongly illuminated than the lower; hence that part is over-exposed. Perhaps the building is situated in a narrow thoroughfare, and possibly the lower part is shaded by the houses opposite.

F. E.—1. We know of no cement which would be reliable. Better get a new dish.—2. We fear the mixture would not dry sufficiently hard. If it do, and the film be not allowed to touch the backing, no injury will result.—3. Most likely your surmise is correct. Try again, and see that the emulsification is complete.

A. HUNTER.—Methylated "finish" can be employed in the manufacture of varnish; but you must bear in mind that it already contains three ounces of some kind of gum to the gallon, and the retailer does not always know what gum it is. Very frequently it is of the commonest possible quality, whatever it may be. We have known common resin to be used. Better commence with methylated spirit.

A PROVINCIAL.—We think it is quite possible that the bronze or imitation gold on the flock paper with which the walls of your reception-room are covered may have something to do with the innumerable small, fading spots on the prints, particularly when you say the prints are mounted in this room immediately after it is swept and dusted. Possibly small particles of the bronze powder become detached from the walls and eventually find their way on to the damp prints; hence the source of trouble. Try the experiment of mounting in another room for a few weeks and note the effect. We shall be glad to learn the result of this experiment.

RECEIVED.—S. Highley, F.C.S.; George Smith; A. F. Genlain; W. H. Harrison; &c.

PHOTOGRAPHIC CLUB.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, September 3rd, the subject for discussion will be—*On the Effect of Different Alkalies in the Development of Gelatine Plates,* with demonstrations.—The Saturday afternoon outing will be at Hale End, leaving Liverpool-street Station at 2.2 p.m.

METEOROLOGICAL REPORT.

CONTENTS.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1270. Vol. XXXI.—SEPTEMBER 5, 1884.

THE DETERIORATION OF GELATINE PLATES.

The question of the deterioration of gelatine plates with age is one of constant recurrence, and one which obviously presents a considerable importance to photographers. It is true that under ordinary circumstances—even supposing, for the sake of argument, that the sensitive film must necessarily deteriorate—the trouble is not one that need cause serious inconvenience, inasmuch as, being warned of the danger, it is within the power of the photographer to employ plates whose character is beyond suspicion. But, on the other hand, it may be beyond the range of possibility that the newness of the plates can be guaranteed, or that they can be used within the period to which their good qualities extend.

For instance, the photographer who is depending for his supply of plates upon commercial sources is, to a certain extent, in the dark entirely as to their age, and can only judge of their quality by actual trial. Yet even he, by systematically noting the number which most manufacturers place upon each box to denote the batch of emulsion from which those particular plates were made, can form some sort of at least approximate judgment of their age. Thus, in a case which recently came under our notice, two batches of plates by the same maker, and purchased at the same time through a dealer, were sent to us for comparison. The results in one case were perfect, while in the other the films had undergone a certain amount of deterioration in the shape of incipient fog at the edges. Upon reference to the respective numbers of the two batches, and knowing the system adopted by the particular maker, we found that there was a difference of nearly three years between the ages of the two samples, one of which had evidently been in the dealer's stock for a very lengthy period.

Then, again, in the case of plates exported to distant parts, or carried on lengthy journeys, to be developed probably months after exposure: it is impossible to guard against the effects of deterioration if such a tendency exist; and hence the importance of studying the question thoroughly with a view to the discovery of the conditions which favour or otherwise the keeping qualities of our plates.

We may at once state, as we have done before, that in our opinion dry gelatine plates do not *necessarily* deteriorate in the slightest degree, and there is abundant evidence in support of that view. On the other hand the fact is indisputable that some films do unmistakably exhibit signs of falling off within a very short period of their preparation, the inference being that the result is caused by some variations in their mode of preparation, probably assisted by the manner of their keeping.

Colonel Stuart Wortley's experience during his trip round the world was distinctly in favour of the stability of his sensitive films. His evidence was to the effect that under extremely trying conditions his dry plates were almost the only things on board that did not suffer more or less from the effects of damp and salt water, and that most of them after a journey of nearly twelve months' duration produced perfect negatives upon development.

What is it, then, that causes the change which is noticeable in so many plates? There can be little doubt that it is mainly caused by imperfect elimination of the soluble products contained in the emulsion; for it is difficult to conceive that a film of pure silver bromide and pure gelatine preserved in a perfectly dry state can possibly contain within itself the elements of decay. But to which of these soluble products are we to look for an explanation of the evil? Possibly to each and all, for even the excess of soluble bromide, restrainer though it be, may introduce a slight element of at least uncertainty.

The chief products of the process of emulsification (other than the silver bromide) to which we have to look are the soluble nitrates formed by double decomposition. The excess of soluble bromide (for we take it that an excess of silver is never under ordinary conditions present) and a certain proportion of decomposed gelatine is produced by the application of heat or by the use of alkali. In the ammonia method of emulsification the alkali itself must be added as a highly important factor, and one or two others that will be mentioned as we go on.

We may here interpolate a few words on the subject of excess of silver, which, as we have hinted above, is seldom or never present as such. The effect upon the keeping qualities of the films of free silver present during emulsification—though subsequently removed by washing—was distinctly shown by Mr. H. B. Berkeley some years ago in a distinct, indeed very marked, discolouration of the whole film, resulting from the mutual reactions of the silver nitrate and the organic gelatine. This, however, is not the description of defect we have to guard against, and free silver in that sense may be set on one side.

But it is nearly certain that the defect is to be traced to the presence of a silver compound other than the sensitive haloid, which is capable of spontaneous decomposition and which is, moreover, readily acted upon by abnormal atmospheric influences. In other words, an organic silver compound of inferior stability to the haloid is formed in some manner during the process of emulsification, and to this the gradual deterioration is due. Let us see what are the chances of such a result.

In the first place, there is to be reckoned the mere contact of the gelatine with the silver nitrate, even though the latter be not in excess of the soluble bromide. If the emulsion be neutral or slightly alkaline the formation of an insoluble organic compound is nearly certain; but if, on the contrary, it be faintly acid the chances are greatly reduced, the compound, if formed at all, remaining soluble, and being thus removed by thorough washing. As might be expected, those films made from ammonia-ripened emulsion are more prone to deterioration than others.

Many operators prefer to mix the emulsion by first adding the silver to the gelatine and afterwards the soluble bromide—a process which would seem to favour the chance of the formation of an organic compound.

But even when the soluble bromide is in excess there exists the possibility of the formation of this inorganic compound, inasmuch as potassium and ammonium and silver bromides are solvents of the silver salt; consequently the emulsion contains a small proportion of dissolved silver bromide which is capable of combining with the gelatine. In the case of an emulsion quickly and thoroughly washed probably no ill effect would arise from this cause, but it is easy to conceive that under opposite conditions danger might lurk. Even the decomposition nitrates exercise a certain solvent action on some of the silver compounds, and their presence in the film may, therefore, contribute towards the tendency to deterioration.

Another and, very likely, the most dangerous of all the ingredients is perhaps the decomposed gelatine, especially when it is accompanied by a trace of alkali. Independent of its deliquescent character, and the consequent aid it thus lends to the work of decomposition, it is a reducer of the silver haloids. One of the best modes of reducing waste gelatine emulsion consists, in fact, in boiling, with the addition of an alkali, when the haloid is rapidly and completely reduced. If this change occur thus rapidly where circumstances favour we can easily comprehend its more gradual and less marked occurrence in the gelatine film, especially when from imperfect storage the conditions are again favourable.

But it is needless to multiply the possible reactions that may tend to produce deterioration; the instances we have given will serve to show that by perfect washing of the emulsion in the first instance nearly every chance of danger is eliminated. Such washing removes entirely all soluble matter capable of forming an easily reducible compound, and the resulting films are thus protected not only from spontaneous internal decay but also from the influence of outside conditions.

From what has been said our readers will recognise the great value of the different methods of emulsifying by precipitation. As a matter of fact we discovered a few months ago in a drawer where they had been exposed to a not over dry atmosphere for nearly five years some plates made by Captain Abney's precipitation process soon after its publication in 1879. They were in every way as perfect as when newly made, though other plates in the same drawer were strongly discoloured at the edges and had acquired a distinctly metallic appearance.

ON THE ARTISTIC MOUNTING OF PHOTOGRAPHS.

It is quite a relief to see that the art aspect of photography is again receiving some little attention, for of late the proceedings of the different photographic societies have chiefly been devoted to the discussion of purely technical matters.

At the last meeting but one of the Photographic Club the topic brought forward for discussion was the artistic mounting of photographs. This subject, though an old theme, is one that has not received that amount of attention on the part of photographers generally, but portraitists particularly, which it deserves. They, as a rule, are still content with the old, conventional style of mounting which has been in vogue ever since the earliest days of photography. We allude to the orthodox cut-out mount with a dome, oval, or cushion-shaped opening, with its neatly-bound gilt bevel and gold line. Now, the employment of these shapes, it may be mentioned, is chiefly confined to photographs, and were in the first instance, doubtless, introduced for the purpose of hiding the defective corners of the picture, caused by the plate being held by the corners during the coating and development or from accidental stains from the corners of the dark slides; and these shapes have been adhered to, more or less, for portraits ever since.

It is very seldom that works of art are seen of these shapes—except occasionally the oval—as they are generally rectangular. This is the shape which is now almost universally adopted for landscape photographs. But our remarks on the present occasion are principally directed to portraits, and these of the larger dimensions. It is true that, since the introduction of the panel and other modern sizes, several of our more artistic photographers have adopted the rectangular shape for their large portraits when they are mounted with a margin instead of being put in a cut mount.

During the discussion at the Club it was generally conceded that photographs on india-paper were far more artistic in appearance than those which are mounted on the imitation tint printed by lithography, particularly when the prints are "plate-marked." India-paper—or, rather, what is called india-paper—and that which is now used even for the finest engravings, it may be stated, is really only an imitation of the genuine article; but it answers our present purpose quite as well, if not better. This paper possesses many advantages over the printed tint beyond that just mentioned, as it may be had in various shades to suit the particular tone of the picture—a great advantage in the case of carbon or platinotype prints—whereas the lithographed tints obtainable in commerce are limited to two or three at most. Again: the india-paper can be cut to any size or shape to suit the individual photograph to be mounted, while the printed tints are only to be had in certain stock sizes, these being somewhat limited, and frequently found to be of a very unsuitable shape for certain subjects.

In all cases where a print is mounted on india-paper it is very desirable that it should be plate-marked; and this necessitates that the mounting be done on plate-paper, as cardboard, unless it be very thin, would require too much pressure to obtain the impression. Good plate-paper mounts always have a more artistic appearance than cardboard, unless, indeed, this be of a much superior quality to that usually employed for the mounting of photographs. If the size be large there will be a difficulty in getting the paper mount flat in the frame; hence the print must be treated in the same way as the better class of engravings are, namely, mounted on linen and a stretcher. This treatment does not remove the plate-mark, but only slightly subdues it, which is an advantage. Photographs of large size thus treated, when suitably framed, are exceedingly artistic as well as effective. It is somewhat surprising that the system of mounting large photographs on linen stretched on a frame instead of cardboard is not more generally adopted when the picture is required with a margin. Pictures so mounted are far more artistic and little or no more expensive, especially for the larger sizes; indeed for the largest sizes it would probably be cheaper than using mounting-boards of good quality.

Steel-plate engravings are frequently printed on a very coarse and rough paper; but, in printing, the pressure renders it perfectly smooth on those portions which come in contact with the plate, leaving the margin of the paper in its original coarseness. Some time since we had a series of photographs mounted on a similar paper and india-paper; they were then rolled with heavy pressure on a steel plate rather larger than the india-paper. By this means the margin of the paper was left coarse and rough, while the print and tint, with a small portion of the plate-paper surrounding it, was rendered smooth and even. This treatment in mounting gave the pictures a very artistic and refined appearance. Whenever india-paper is used the print should always be trimmed the same shape as it—which, for artistic effect, should in most cases be rectangular. It is clearly a mistake to trim the print to a dome or cushion shape and then mount it upon a rectangle, though this is frequently done.

There is no reason whatever why the photograph itself should not be printed with a margin an inch or so wide, provided the negative be masked up sharp and evenly. In the finished print the margin would never be really white, so that when the photograph is put upon the mount the margin will always show a more or less delicate tint, which, as a rule, harmonises with the picture admirably. We have seen some carbon pictures—copies of drawings—on rough paper, printed with a broad margin, so that they did not require a separate mounting. They were simply pasted on to a linen stretcher, and put into a plain, flat, unpolished oak frame, with a narrow gold bead inside. The general effect of the picture was very artistic and most unphotographic in appearance. The prints being of a sepia colour, and on the rough drawing-paper, were very close imitations of the original drawings.

We recently saw some large-sized portraits which had been most artistically treated in the mounting and framing. The prints themselves were in platinum and (black) carbon. They were placed behind very thick cut-out mounts with rectangular openings, and instead of the bevils being gilt, after the orthodox fashion with photographic mounts, they were left white, as is usually the custom with mounts for water-colour, or pencil drawings. They were then framed in simple black and gold frames. The pictures themselves were very artistic productions, and these qualities were still further enhanced by the *recherché* style of mounting and framing.

No apology is necessary for once more directing attention to the real importance of so apparently trivial a question as the mounting of photographs, seeing the marked effect for better or for worse the style of mounting may have on the finished picture. It is grievous to see it, but it frequently happens that a picture which has received the most artistic treatment in its production is completely spoilt by injudicious mounting and framing.

We hope to take an early opportunity of giving some practical hints on mounting on linen and stretchers, on india-paper, and also a simple method of plate-marking.

THE FADING OF COLLODION IMAGES.

If there be one doctrine or dogma in photography held more strongly than another by the fraternity it is that of the stability of a collodion image. Practice and experience have confirmed what theory had pointed out, namely, that the atoms of metallic silver, of which the collodion image consisted, should remain imbedded in the innocuous collodion filament in which they were formed without undergoing any change whatever.

We know that in pyroxyline spontaneous decomposition sometimes occurs. This is usually due to the employment of a very high temperature in its preparation, and to the acids not having been thoroughly removed. In such a case an atmosphere of red fumes will be found in the bottle in which it is kept, caused by a partial liberation of the oxide of nitrogen. It would be a subject of too protracted a character were we to here investigate the behaviour of such pyroxyline after it became converted into collodion, carrying still further investigation into its state when, after having been subjected to those operations in the course of which it became the recipient of an image, it eventually found its consummation in a horny pellicle in which were imbedded, both on its surface and throughout its substance, granulated atoms of silver.

Despite all theories to the contrary, collodion images, as they exist in everyday photographic life, are occasionally found to fade, and in some instances to fade badly. This is not necessarily dependent upon any deleterious influence or action of the atmosphere, as it occurs when the image is completely isolated from the influences of air. For example: some of the early specimens of microphotography exhibited at a meeting of the London Photographic Society on November 5, 1857, and to which we have access for examination, show serious indications of fading, one of them in particular—a portrait of the then President of the Society, the late Sir Frederick Pollock, Lord Chief Baron—although smaller than a pin's head, and protected from the atmosphere by a thin glass covering plate cemented by Canada balsam to that which contains the picture, has faded to such an extent as to show (when examined under a microscope) innumerable spots all over the background, a portion of the face and figure having disappeared altogether. And yet this tiny photograph has lain closely imbedded in resin, or hardened Canada balsam, from the day it was produced, now nearly twenty-seven years back, which demonstrates that the agent of destruction did not in this case come from without, but had been imbedded within the photograph itself.

Conversing with one of several photographers, at present on a visit to England, as to the causes of the reported collapse of the attempts lately made to get collodion transfers naturalised in the United States, he said that a *fama* exists against them there in consequence of their liability to fade—not alone in the colouring, as had already been described by one of the correspondents of the British Journal of Photography, but in the substance composing the image itself.

With regard to the fading of the transparent oil pigments with which the faces of such transfers are treated by way of being painted, especially in climates where the sun's rays are powerful: this, we imagine, is one of the inevitable accompaniments of low-priced work. A transfer painter, who lately called to show us specimens of his work, spoke of nine shillings per dozen as the remuneration given in some establishments for finishing an ordinary 12 × 10 portrait in oils. But neither the artistic merit of the painting nor the permanence of the colours concerns us at present, our inquiry having reference to the causes why the collodion transfer, *as a photograph*, should, under some circumstances, succumb to the influence of time with the great rapidity alleged by our American friend to be found sometimes in his country.

Watching carefully a workman reported to be skilful in producing transfers of a good quality, we observed several things that would go a long way in accounting for the speedy destruction of the transfers. One of these was the obtaining of a fine tone by sulphur.

The workman in question—who was a mere manipulator, and did not appear to possess any more chemical knowledge than sufficed to weigh out and mix the compounds he used—stared when we spoke of sulphur toning. When, however, we made inquiry as to his reasons for fixing his enlargements in an old hypo. bath, charged with silver not only from its solvent action upon the iodide, but from the addition made to it, with every plate immersed, of pyrogallic acid, citric acid, acetic acid, and nitrate of silver—for it was part of the routine system of operations that the image was not to be washed previous to its immersion in the fixing bath, but must be transferred direct just as it stands—he replied that such was the system universally adopted and insisted on at the establishment where he had long practised transfer making, and where the trifling remuneration given—from sixpence to a shilling a dozen for 12 × 10 size—prevented the workmen from being squeamish as to the stability of their work provided a good tone was obtained.

But this was not all we saw. The enlarged sulphur-toned transparency having been rinsed to remove the so-called hyposulphite-of-soda solution, was then placed in close contact with a sheet of transfer paper coated with gelatine and alum, and placed in water until it was flaccid, in which state it was rubbed into close contact with the wet collodion image and allowed to remain for several hours, or until both were quite dry, after which the paper, to which the image was now attached, was stripped from off the glass, pasted or glued to a card, and passed into the hands of the painter.

If a premium were offered for a process which should ensure the briefest possible tenure of existence to a photograph, we question if it could be found in the ability of any photographic chemist to devise or suggest one which would more completely fulfil the conditions than that which we have here described.

But, although in practice, and when conducted under the circumstances narrated, the collodion transfer process may be totally unreliable, it does not, by any means, follow that it may not be one of the most stable of all methods, and yield results which are practically durable. Several writers on this subject have spoken of this quality as pertaining to transfers, and seeing it can so easily be secured it is a pity that those who have to produce enlargements under climatic influences which favour fading, or by which such incipient seeds of fading as may be present in the photograph become rapidly developed, do not adopt all precautionary and preventive measures to prevent these seeds of consumption from germinating.

The most beautiful enlarged collodion photographs are not necessarily the most permanent—an assertion not likely to be gainsaid for a moment by those who still retain in their possession any of the once beautiful photo-crayon enlargements which, when introduced by the late Mr. Oliver Sarony many years ago, caused such a *furore*. But, as in these photo-crayons it was afterwards found to be possible to combine permanence with beauty, so is it in the case of the collodion-transfer process, which is but a very slight remove from that to which we have just alluded. To this subject we may hereafter return.

FRILLING AND ITS CURE.

From the earliest days of gelatine dry-plate photography frilling of the film—whether assuming the form of the true frill (that is, a swelling, sometimes to extreme dimensions, of the edge of the film, thus causing it to assume the well-known and well-described appearance) or taking the shape of blisters of various sizes—has been an evil dreaded by all. Rarely has a photographer a summer's experience without a single example of the evil, which, when it does make its appearance, proverbially spoils the best negative of the year, Innumerable nostrums have been tried and recommended in the shape of prevention; but in practice they are mainly reduced to the employment of an alum, either in the manufacture of the emulsion or as an after-treatment when the plate has been destroyed. There are well-known dangers in connection with the former method, while the latter is objected to in consequence of the increased length of time that must be devoted to a negative before it can be considered as past the finished stage.

There is no doubt that a much greater immunity from this evil characterises the plates now to be procured from the dealers; but, notwithstanding the greater knowledge obtained by practice, combined with judicious discrimination in the choice of gelatines, frilling is by no means a thing of the past. The alum bath used before fixing is, however, effective in almost every case, and we have already published the advantages of a thorough draining of the hypo. before washing the plate after fixing. The only objection to this useful method is the danger of allowing the draining to continue for too long a period, when, with some class of film, the image is slowly attacked, a plan, by-the-bye, which enables it to be of considerable use in reducing the strength of an over-dense negative if left for a very considerable length of time—say a whole day, for instance.

Sulphate of magnesia has been much spoken of; but, apart from any objections to its quality of being precipitated by the ammonia of the developer, we have found, after many inquiries, that scarcely any photographer makes use of this remedy.

When a particular batch of plates is in the uniform habit of frilling, if the owner do not cure them with a hammer he can generally avoid losing a negative by treating every plate with alum before fixing. The chief danger of losing a plate happens when a case of frilling suddenly and unexpectedly occurs. Some dozens or hundreds of a particular make have behaved to perfection in this respect, and a frilled negative is the last thing thought of; but on some special occasion—an extreme elevation of temperature, an unusually prolonged development, or from no known cause at all—the negative when taken out of the washing water is seen to be ruined, covered over with blisters of all sizes, or the film bloated and expanded at the edge—one huge excrescence, perhaps, reaching the middle of the plate. Or, what is worse, the same appearance may be presented upon the first rinse with the washing water while all the hypo. remains in the film.

We have not, however, been drawing pictures of troubles which our readers know are not imaginary without having a remedy to suggest. To Mr. Watmough Webster we are indebted for details of a method which, in the short time we have had to try it, has shown itself to be a perfect cure for a highly-developed state of frill and blister. We cannot do better than to describe the trial we gave the plan. Taking a twelve-by-ten rather under-exposed plate we developed it for a lengthened period, slightly focussing with ammonia and using water at a temperature of about 60° Fahr. After fixing, without any preliminary treatment with alum, we placed it under a rose to wash, and finally allowed it to soak in a dish of water, thus affording every chance for the formation of frill in a plate disposed that way.

After a time a blister about an inch in diameter formed in the middle of the plate, and a large frill about three by two inches at the edge—not a very terrible state of affairs, it may be said, yet sufficient to spoil any negative where, as in this case, important detail was included. Under ordinary circumstances this frill and blister would have dried down different in texture and with sundry creases.

Our next step was to place the frilled negative in a solution of alum, leave it there for an hour, and then well wash. After washing we removed the superfluous water with a dry cloth (of course, avoiding touching the raised film), and placed the plate in a dish of methylated spirit. At the end of a couple of hours we did not seem to have gained much, so covering the dish with a sheet of glass we left the negative soaking in spirit all night. The next morning not a trace of frill or blister was left, and, after drying, the closest examination fails to reveal where either blister or frill had been. There is no alteration in the density of the image, no puckering or falling into ridges, and, in fact, in every sense the negative appears perfect. If, as we have no reason to doubt, this method of Mr. Watmough Webster's should be applicable to all cases of frilling, however strongly developed, it will be of the greatest practical importance, as there cannot be a doubt that instances are numerous where fine negatives have been rendered utterly worthless from frill or fine blisters. On portrait negatives with plain backgrounds, though the negative may be put to dry at once when the blisters are discovered, the ordinary mode of treatment always leaves evidence of their presence behind; but the spirit treatment rapidly takes them away, and permits the negative to dry without leaving a trace of their presence.

It will also assist in adding to the keeping qualities of negatives; for we do not doubt that there are many valuable negatives stored by photographers already in a state of incipient disintegration through having been washed and dried long before the hypo. had been removed so as to avoid the spreading of blisters and frills, which, as is well known, are liable to spread with startling rapidity very soon after their first formation. Now, in a frilling case, the washing may be prolonged for a time sufficient to get rid of the main part of the hypo. Alum solution may follow to decompose the last trace of hypo. and to arrest further frilling; the soaking in spirit will then eradicate the evil already present.

We anticipate the method will be well tried by many of our readers, and we trust they will, for the benefit of others, send us an account of their success.

The Presidential Address at the British Association meeting having been devoted to physical science, it will be readily inferred that photography was closely allied to many of the subjects touched upon. It is not often that a striking novelty is introduced in this part of the proceedings, the President usually confining himself to a *résumé* of the progress made in the science on which he treats. It goes without saying that accuracy and lucidity characterised the address of Lord Rayleigh, than whom it would not be possible to find a more suitable exponent of science, from the double standpoint of theory and practice.

The science of optics, it is well known, is one to which his lordship has devoted special attention and it is interesting to note that the important *rôle* played in it by photography forms the opening part of the portion of his address given to optics. We have from time to time kept our readers thoroughly *au courant* with scientific discoveries relating to photography as they have been published by their authors, so that to keen readers of this Journal the topics dwelt upon by the President will not be unfamiliar. He said:—

The mystery attaching to the invisible rays lying beyond the red has been fathomed to an extent that a few years ago would have seemed almost impossible. By the use of special photographic methods Abney has mapped out the peculiarities of this region with such success that our knowledge of it begins to be comparable with that of the parts visible to the eye. Equally important work has been done by Langley, using a refined instrument of his own based upon the principle of Siemens's pyrometer. This instrument measures the actual energy of the radiation, and thus expresses the effects of various parts of the spectrum upon a common scale, independent of the properties of the eye and of sensitive photographic preparations. Interesting results have also been obtained by Becquerel, whose method is founded upon a curious action of the ultra-red rays in enfeebling the light emitted by phosphorescent substances.

Attention is called to Professor Langley's remarkable investigations upon the part played by atmospheric absorption in altering the colour of the sun as seen from the earth, which show that to an eye situated outside the atmosphere the sun would present a bluish tint. He said it would be interesting to compare the experimental numbers with the law of the scattering of light by small particles given some years ago as the result of theory. Though he does not refer to this phase of the subject there is no doubt that a special interest attaches to it at the present time on account of M. Montigny's weather prophecies, which, fulfilled as they have been, and connected with this point, naturally excite considerable attention in this direction.

Lord Rayleigh avoided all but a very slight reference to chemical subjects; hence Professors Liveing and Dewar's researches into the ultra-violet portion of the spectrum—which are closely connected with the chemical constitution of bodies, and which have been carried on almost entirely by photographic aid—are dismissed by the remark that the subject is too large both for the occasion and the individual. Lord Rayleigh, however, distinctly foreshadows a great change in the mode of viewing chemical action in the future.

It is well known that there is often uncertainty in spectrum indications as to whether certain lines are due to matter in the sun, or whether they are not rather due to absorption in the terrestrial atmosphere. Hitherto the point has only been able to be settled by observations of the sun taken at different altitudes; but, by a method founded on a combination of principles enunciated by various investigators, a plan has been devised which enables the determination to be quickly made. The President's own words may be quoted. Speaking of this "beautiful application of an idea of Doppler," he says:—

If a vibrating body have a general motion of approach or recession the waves emitted from it reach the observer with a frequency which falls short of the real frequency of the vibrations themselves; the consequence is that, if a glowing gas be in motion in the line of sight, the spectral lines are thereby displaced from the position they would occupy were the gas at rest. * * * But the sun itself is in rotation, and thus the position of a solar spectral line is slightly different according as the light comes from the advancing or the retreating limb. This displacement was, I believe, first observed by Thollon; but what I now desire to draw attention to is the application of it, by Cornu, to determine whether a line is of solar or atmospheric origin. For this purpose a small image of the sun is thrown upon the slit of the spectroscope, and caused to vibrate two or three times a second in such a manner that the light entering the instrument comes alternately from the advancing and retreating limbs. Under these circumstances a line due to absorption within the sun begins to tremble as the result of slight alternately opposite displacements. But if the seat of absorption be in the atmosphere it is a matter of indifference from what part of the sun the light originally proceeds, and the light maintains its position in spite of the oscillation of the image upon the slit of the telescope.

A brief statement of an important law regarding prisms and gratings is given:—"The optical power in gratings is proportional to the total number of lines accurately ruled without regard to the degree of closeness, and in prisms that it is proportional to the thickness of the glass traversed." * * "The magnificent gratings of Rowlands," Lord Rayleigh states, "are a new power in the hands of the spectroscopist, and as triumphs of mechanical art seem little short of perfection."

Our readers may remember that, a few months ago, we gave the results of experiments made by Messrs. Young and Forbes, which showed that light varied in the rapidity of its propagation according to its colour or wave-length. "Such a variation is opposed to all theoretical evidence," the President stated, and could only be accepted on the strongest evidence." Such a disturbing conclusion, however, has not been accepted, and Mr. Michelson had informed Lord Rayleigh that he has recently repeated his experiments with special reference to the point in question, and has arrived at the conclusion that no variation exists comparable with that asserted by Messrs. Young and Forbes. The actual velocity was found to be, as before, 299,800 kilometres per second.

This question of the lengths of light-waves has long been connected with that of the thickness of soap-bubbles. "It is remarkable," says the President, "how the playthings of our childhood give rise to questions of the deepest scientific interest. The top is, or may be, understood; but a complete comprehension of the kite and of the soap-bubble would carry us far beyond our present state of knowledge. In spite of the admirable investigations of Plateau it still remains a puzzle why soapy water stands almost alone among fluids as a material for bubbles. * * * When the thickness of a film falls below a small fraction of the length of a wave of light the colour disappears, and is replaced by an intense blackness. Professors Reinold and Rücker have recently made the remarkable observation that the whole of the black region soon after its formation is of uniform thickness— * * * between seven and fourteen millionths of a millimetre, so that the thinnest films correspond to about one-seventieth of a wave-length of light.

An interesting reference is made to the radiometer, that instrument —wonderful after all—of which such great things were expected in photography. It is well known that the investigation carried on by Mr. W. Crookes with regard to this instrument led to the construction of what was practically an entirely new instrument—the pump for obtaining extremely high vacua. With regard to the resistance of the contained air to the vanes some most interesting facts are given. "Maxwell drew the startling conclusion that the viscosity of a gas should be independent of its density—that within wide limits the resistance to the moving disc should be scarcely diminished by pumping out the gas so as to form a partial vacum. Experiment fully confirmed this theoretical anticipation—one of the most remarkable to be found in the whole history of science. * * * Subsequently the law has been examined by Crookes, who extended his observations to the highest degree of exhaustion. Perhaps the most remarkable results relate to hydrogen. From the atmospheric pressure of 760 m.m. down to about half a m.m. of mercury the viscosity is constant."

It is matter of congratulation for photographers that practically they were not involved by the electrical speculative mania which has had so much to do with the "low water" in which electric illumination now stands. Companies being wound up, and public lighting, in many places, having turned out a practical failure, form a very pointed contrast to the glowing anticipations of a few short years ago. Notwithstanding all this Lord Rayleigh is most hopeful about the future of electric lighting. Photographers take a pride in the linking of the name of Swan—eminent among photographic inventors—with the foremost men of science of the day.

We could not do better than conclude our *résumé* of the photographic points of the discourse by giving the President's remarks upon inventions and inventors, which are pregnant with suggestiveness in regard to various matters that have recently been brought into prominence in the photographic world:—

By a fiction as remarkable as any to be found in law, what has once been published, even though it be in the Russian language, is usually spoken of as "known," and it is often forgotten that the rediscovery in the library may be a more difficult and uncertain process than the first discovery in the laboratory. * * * In making oneself acquainted with what has been done in any subject it is good policy to consult first the writers of highest general reputation. Although in scientific matters we should aim at independent judgment, and not rely too much upon authority, it remains true that a good deal must always be taken upon trust. Occasionally an observation is so simple and easily repeated that it scarcely matters from whom it proceeds; but, as a rule, it can hardly carry full weight when put forward by a novice whose care and judgment there has been no opportunity of testing, and whose irresponsibility may tempt him to "take shots," as it is called. Those who have had experience in accurate work know how easy it would be to save time and trouble by omitting precautions and passing over discrepancies, and yet, even without dishonest intention, to convey the impression of conscientious attention to details.

LIME-LIGHT EXPLOSIONS AND THEIR PREVENTION.

My last article on lime-light explosions was intended to conclude the subject; but now that the lantern season is drawing near the manufacturing opticians are beginning to be interested, and I have been asked to make further experiments.

A jet with safety arrangement in the front, near to the place usually occupied by the mixing chamber, appears to be a desideratum, and my first trials in that direction were not satisfactory. Mr. W. Broughton, the inventor of the ethoxo process, tells me also that he began by filling the mixing chamber of his jet with pumice granules, but afterwards discarded that method in favour of the tubes. My own jet was made to pass the gases through the granules before they entered the mixing chamber, but the forcing action proved to be greater than when the granules were in tubes attached to the taps of the jet. I have now, therefore, altered it in such a way that I can place the mixing chamber either above or below the granules, and have thereby obtained interesting results.

No. 1. Pulverised glass, screened by two sieves of forty and fifty meshes to the inch respectively, in a tube half-an-inch wide and half-an-inch long, with a mixing chamber holding about one and a-half fluid drachms of water between it and the nipple. The exploding flame of ethoxo gas was arrested three times consecutively, but on the fourth trial it passed through the granules and destroyed the balloon.

No. 2. Same as No. 1, but commercial granulated brass, screened by sieves Nos. 24 and 30, used instead of pulverised glass. The flame passed through on the first trial, the granules being too coarse for a tube so short as half-an-inch.

No. 3. Same as No. 2, but with finer granules of brass, the sieves being thirty-six and sixty meshes respectively. Flame arrested and could not be driven through by repeated trials.

No. 4. Same as No. 3, but the front part of the jet heated by a spirit lamp until it became as hot as it would be likely to be from the heat of the lantern at the conclusion of a two-hours' lecture. The flame now passed through the granules on the first trial.

No. 5. Same as No. 4, but the mixing chamber placed *below* the granules, and only enough space left above for the free passage of the gases. Flame arrested, and could not be made to pass after many trials.

No. 6. Same as No. 5, but pulverised glass used instead of metallic granules. Flame still arrested, although the jet was hotter than the hand could bear.

No. 7. Same as No. 6, but an india-rubber suction ball attached to the O tap, the balloon being on the H tap of the jet. The result was that as soon as the suction was applied the flame disappeared from the orifice of the jet, and the whole of the explosive gas passed out of the balloon, through the mixing chamber, back into the ball, but without igniting. This experiment was intended to imitate the falling off of a weight from one of the bags in the oxyhydrogen process; only in that case the gas is not sucked back by the bag from which the weight has fallen, but is *forced* the wrong way by the bag still loaded. The experiment, however, shows that if there were any suction it would relieve itself at the expense of the other bag, and would not draw the flame through the safety tube.

No 8. A repetition of No. 7, with brass granules instead of glass. Passage of the gas in the wrong direction as before, but flame arrested and no explosion in the balloon.

No. 9. Granules of pumice used in the front part of the jet instead of glass or metal. Flame well arrested, independently of the position of the mixing chamber; but I observed a tendency to a slight flickering of the flame, which makes me think that granules of a *dusty* kind are not so suitable when they have to be placed very near to the orifice of the jet.

No. 10. Two safety tubes three-quarters of an inch long and half-an-inch wide, filled with pumice granules screened by sieves of forty and fifty meshes respectively, and placed on the nozzles of the dissolver of a large biunial lantern. The jets and tubing of the lantern were then filled with explosive ethoxo gas by the aid of a second lantern, and a free stream of the gas kept up until all the air had been effectually expelled. The gas was then fired, but the explosion stopped at the pumice and did not destroy the two balloons on the other side. On examining the pumice granules I found them *blackened* at the end nearest the lantern, and partly powdered by the violence of the explosion.

No. 11. The same in every respect as No. 10, but with fresh ethoxo gas very carefully graduated to the most explosive point. Flame still arrested on reaching the pumice.

No. 12. Same as No. 11, but with the pumice chambers removed. Flame rushed back and blew the balloon to pieces as soon as the pressure began to relax.

From the results obtained in these experiments I am satisfied that a jet can be made with which no explosion would be possible. I mean, of course, an explosion lighted up by the flame in the lantern itself. A mixture of the two gases in one bag or a rent in the india-rubber tubing must always be a source of danger when the reading lamp or any other light is at hand; but accidents of this kind are very rare compared with the other. If I can show that granules of pulverised glass, which do not stand in the first rank of flame extinguishers, arrest the flame (and these granules weakened still further by heating with a spirit lamp and applying suction), no apprehensions, I think, need be entertained that such a safety chamber will fail in the hour of danger.

I append the following directions for making a chamber of this kind beneath the orifice of the jet. It must be half-an-inch wide and half-an-inch deep interior measurement, with a disc of wire gauze, fifty meshes to the inch, resting on the top. This disc must be five-eighths of an inch across, and be kept in its place by a ring of wire. Two discs of gauze—one of fifty meshes, and the other of twenty-four meshes to the inch to strengthen it—must be pressed upwards against the bottom of the chamber by another ring fitting into a groove in the brass; whilst below there should be an empty space holding about two fluid drachms, in which the gases may mix before they enter the granule chamber. Above the granule chamber is no cavity of any kind, but the cap screws down nearly close, leaving only a space of about one-eighth of an inch extending quite across, and in the centre a tube of the same diameter leading to the orifice.

Two other points must be carefully attended to, namely to make the discs of wire gauze easily removable without disturbing the jet, and to keep a free passage for the gases. The great difficulty will be not in arresting the explosive flame, but in getting enough pressure with one hundredweight on the bags; and, therefore, no attempt must be made to contract the diameter of the granule chamber at the top in order to economise space. The upper disc of wire gauze must be as large as the lower, and all the discs must be changed if they should become rusty or choked up. Very little time need be occupied in doing this; and I find that I can take my granule chamber out of the lantern, put in fresh granules, and screw it down again upon the leather washer in two or three minutes, whilst I lose no more than twenty or at the most twenty-five per cent. of pressure. The reason that some complain so much of want of pressure I believe to be that they do not keep their apparatus *gas-tight* in every part, so that much of the pressure is lost before it reaches the orifice of the jet.

I shall not be surprised to find on further trial that the light is somewhat improved when the safety chamber is in the front part of the jet. The gases will certainly be heated by passing through the granules in that position, and this ought, theoretically, to be an advantage.

It has occurred to me, also, that the light in the blow-through process might be increased by filling a part of the oxygen tube of the jet with coarse granules of metal. The heat of the lantern would then enable you to blow a hot instead of a cold blast into the centre of the hydrogen. T. FREDERICK HARDWICH.

SODA DEVELOPMENT.

THE experience of many is the best test of the value of a process. Since Mr. A. F. Genlain so strongly advocated the use of soda instead of ammonia for the development of gelatine plates many have, no doubt, given the plan a trial; and, if their experiences were published, I feel certain that the advantages of the method would be approved by the majority. Some time since I tried soda, but the colour of the negatives was disagreeable; a yellowness all through lights and shadows alike (indicating slow printers) prejudiced me against its use. I afterwards saw some excellent negatives free from this objectionable tint, and was induced to give it another trial, the results of which were so satisfactory that I have now entirely discarded the use of ammonia and adopted soda in its place with much advantage, the printing qualities of the negatives being so vastly improved.

In every case where two negatives of the same subject taken under the same conditions were developed—one with soda and the other with ammonia—the soda-developed one has proved the best printer, although, perhaps, not so nice-looking as a negative. The appearance of a negative, however, matters little so long as its printing qualities are satisfactory.

One advantage of soda over ammonia is—much less tendency to blurring when strong light is in close proximity to shadow. It will not, however, prevent it (for the fault is, in a great measure, dependent on the character of the film), but certainly reduces the evil to much smaller proportions. There is also a greater and more equable gradation of tone from clear glass to opacity, thus giving a better *quality* of print.

One of the most objectionable faults in gelatine negatives has been want of atmosphere—a quality principally dependent upon the range of tone. It is a shortcoming very conspicuous in landscape work, where we see middle distance as strongly pronounced as the foreground, and the extreme distance dense as the sky. Most photographers know this effect, which in some systems of development and with some plates it is impossible to avoid; but unless it be the work must be considered imperfect. This is the *wet-plate* quality so often alluded to, and in the greater part of gelatine negatives so seldom seen.

Much greater control can be exercised over the development when soda is used than when the alkali is ammonia. Even a much over-exposed plate comes up slowly, giving time for the addition of a restrainer in the form of citric acid or bromide of potassium, solutions of which may be kept ready to hand. For my own part I am an advocate for full exposure, and, in consequence, sometimes overdo it. Nothing, however, actually makes up for a right exposure. Although a considerably over-exposed negative may be made to give a good print, it will be a very slow printer; whereas a properly-exposed one would produce a print equally good in a fourth of the time. This fact alone, when many prints are required, is of considerable importance.

The proportions of the chemicals used must be suited to the plates, and can only be determined by actual experiment. I have found *three* parts of a *one*-grain solution of pyro. and bromide of potassium, mixed with one part of a twenty-per-cent. solution of soda, a good standard formula for the plates I am employing. This can be varied by using a greater or less proportion of soda—the more soda the greater softness, and *vice versâ*. The negatives are improved in clearness by a bath of chrome alum and citric acid.

EDWARD DUNMORE.

TRANSATLANTIC JOTTINGS.

READERS of American photographic periodicals are familiar with the picture of a gentleman seated upon a remarkable chair, surrounded by apparatus, and about to give the *coup de grace* to a picture lying before him: the accompanying letterpress informs us that he is manipulating an "air-brush." It is a species of art by machinery, of which, nevertheless, good accounts have been given by experts. There is, however, now advertised a rival to this piece of apparatus in an automatic retouching machine patented at the end of last year, which, from the illustration appended to it, appears to work by a pulley and treadle; the former, attached to the end, is the pencil, and the retoucher works away what appears very like a sewing-machine. This invention also appears to have many admirers.

We know America to be the land of labour-saving machines; hence we should not be surprised at anything of the kind there to be bought. Perhaps the most remarkable contrivance in this direction is Major Hill-Wilson's automatic printing-machine. Strips of sensitive paper are placed within the instrument along with a negative, when, by the aid of clockwork, it turns always to the light, clamps the paper *in situ*, and then the whole is allowed to work by itself, nothing being further needed than to empty the prints at the conclusion of the day's work. The clockwork moves at a varying rate according to the sun's altitude; the nearer the time approaches midday the quicker the machinery goes. This may be useful; but when a few hundred negatives were required to be printed from in a day, we think the machine would be found in the way, not to speak of the outlay needed. The machine is not reported to equalise the light.

Among new processes is Dr. West's suggestion for a new mode of printing, the chief recommendation of which appears to be its novelty, as there would scarcely seem to be a commercial future for pictures of a beautiful crimson colour. He says:—"Paper, silk, or other fabrics floated in a solution of diazo-salicylic acid, or one of its salts, dried, printed, and washed with water, shows an image of a beautiful crimson colour." He gives detailed instructions for making the compound, but these we, perhaps, need not repeat. At the same time we quite agree with the editors of Anthony's *Bulletin*, in which the account appears, that "all fields, however unpromising they may appear, deserve exploration, and hold out great inducements, especially in the direction of a good and easy printing process."

The editor of the *Photographic Times* (New York) resuscitates the old process for restoring faded prints by means of immersion in a bath of bichloride of mercury (one grain to the ounce). He gives the very wise caution to anyone about to undertake the operation to take the preliminary step of making a negative from the print and a transparency from the negative, retouched and compared with the original, before taking any step towards the recovery of the lost beauties of the print. This, as we say, is wise, seeing that under some conditions the picture, instead of darkening and brightening, fades entirely away under the action of the bichloride.

That is a capital suggestion also (which, indeed, is more than a suggestion, since he has carried it out in practice) to carry the possibilities of a series of expensive lenses by the simple plan of using, in conjunction with one doublet lens, one or other of a series of concave lenses to lengthen the focus to any extent at will, the lenses being mounted over apertures in a long brass slip passing through a perforation made in the lens mount for the purpose.

The following rich extract appears as quoted from the columns of a newspaper, and is said to represent an experience of a photographer who was being introduced by the writer. We cannot, of course, vouch for the *bona fides* of the story, but it is too good an example of the bounce of the country to miss:—

"I tell you, pictures do a great deal to make a man popular, especially if he's good looking. Not long ago a handsome gentleman from a neighbouring city came here for photographs. Before he left I ascertained that he was a candidate for a high office. 'Let me make you enough pictures and I will elect you,' I said, for he made a very taking picture. He ordered an extra lot, but not enough. I afterwards heard that he was beaten by about sixty majority."

We find, too, a quotation from the *Deutsche Photographen Zeitung*, which is almost appalling from its cynical effrontery. It is a reply from an employer to the complaints of his *employés* that twelve hours' daily labour, not excepting Sundays and holidays, is too much to ask.

Employer.—Our young men can have no ground for complaint. Anybody embracing photography as a profession should make up his mind to renounce all desire or demand for holidays and Sundays. These are the days on which the majority of the people come to be photographed; thus the business is kept going, enabling us to engage and pay assistants. I have been an operator for ten years, during which time I have never known such a thing as a holiday, do not not know any now, do not desire to know any; in fact, would be uncomfortable were I to take one, and we do not hire help for mere pleasure. Our retouchers lead a comfortable life. They have abundance of freedom. Operators and printers must content themselves with rainy days. Should it happen they are really required to work twelve hours a day there is still time enough for them to eat, sleep, and rest.

If this be a real picture of the state of things on the continent, in even a small number of studios, we can only liken it to white slavery.

Professor Hugh, at the Chicago Photographic Association, gave an account of some experiments he had been making with a new sensitometer of his invention. It occurred to him that a good sensitometer might be constructed by making a scale of numbers and arranging it so that different parts of the scale received varying amounts of light, and he therefore constructed such a scale and placed in front of it a black revolving plate cut into the form of the "snail" used in the striking part of a clock. As this revolved, that part of the scale which was nearest the circumference of the circle of rotation (the scale being arranged radially) would receive the greatest quantity of light, the nearest the centre the least. The disc was revolved by means of clockwork (speed was not material), and while it was in motion a negative was made of the entire apparatus, when the *lowest* number visible after development gave the degree of rapidity of the plate. There seems to be the nucleus of something good in this device; but the general sense of the meeting seemed to be against it on account of the want of a standard light, the Professor himself stating his experiments, so far, to have only been comparative.

TOURISTS' CAMERAS.

MR. W. H. HARRISON was particularly unfortunate in his reference to the opinion of the late Mr. H. Baden Pritchard on the subject of tourists' cameras. It is an open secret that the latter was the author of *A Trip to the Great Sahara*, in which occurs the wail of agony about the inefficiency of his particular tourist's camera. Of course, from the peculiar point of view which he took of the requirements in a tourist's camera there was a good deal of cogency in his remarks; but I venture to say that if time had been given to him he would have regretted having taken that particular point of view, and, consequently, the inferences he drew.

I will grant at once that there are plenty of cameras in the market which are utter abominations, always failing at the time of need, except for the most ordinary, straightforward work. The reason is not far to seek. For many years the principal demand was for wide-angle lenses, and, consequently, shorter cameras. Longer-focus cameras were in the market, but such was the strange infatuation that rectilinear lenses were absolutely necessary that very few cared to go to the expense, as well as the weight, of the extra lenses necessitated by the more complete camera; and as demand must, as a general rule, precede supply, demand was found to be in the direction of short focus, the energy of makers was devoted to what became a current trade article, and also, in inevitable consequence of the demand, to making the camera as showy in external appearance as possible.

If, as I imagine, Mr. Harrison is possessed of one of these cameras he is to blame for not ascertaining for himself what his real requirements were before purchasing; and yet not to blame, for how could he gain the necessary knowledge except by experience? If he will consult the advertising columns of the photographic journals he will find that there is an earnest desire on the part of the real makers to meet the wishes of the public—particularly of amateurs. Speaking as one of them I can affirm that it is to amateurs, far more than professional photographers, that we look for real progress, and that every important hint of increased efficiency is eagerly watched for and instantly adopted.

Ordinary trade runs in very different grooves. The general tendency is only towards that amount of change which will give better outward appearance and economy of production. It is a question *entirely* of profit. If a dealer can produce an article which looks better worth the money, and on which he can secure a greater profit, he will not hesitate to aver that it is superior in every respect to another on which he obtains less profit. It is not always from pure greed that he does this. Probably he is, in reality, utterly ignorant of the practical value of the article, and speaks conscientiously from a commercial point of view, because he finds that they sell better. This is not to be wondered at; for how can the amateur know the good or the weak points of his apparatus until he has been taught by failure? He, therefore, in ninety-nine cases out of a hundred, fortified by the dealer's intentional or unintentional misinformation, chooses the showy apparatus, and then laments that brains have so little to do with the construction of tourists' cameras. If he would seek out the maker and take him into his confidence as to his requirements he would find but little difficulty in obtaining a camera to his mind.

It is absolutely impossible for a camera to be designed that will suit everybody's ideas of their requirements. I know, as a fact, that one of the very best camera-makers finds it impossible to make stock. He has, from the very nature of his business, been in daily communication with people who think they know what a camera should be and are not afraid of paying for it. Surely a man in this position ought to be in possession of such a collection of hints and notions that he could combine a camera which should be above suspicion of inefficiency, for this would enable him to make stock. Yet it is not so; his customers *will* have their special "fads" carried out. Whether they turn out to their complete satisfaction or not he probably seldom learns. I am inclined to say that the brains in insufficient supply are those of the users rather than the makers. They only think they know, and rush into print without ever really having thought the thing out from a practical point of view, which the maker must necessarily do before he can commence to put it in execution.

Now take Mr. Harrison's suggestion—that the camera should be packed inside the case ready for use. Note that the camera should be capable of racking out to three times the length of the longest plate it will take, and that both ends of the case are to be made to pull out so as to expose both lens and focussing-screen to view. Well, the case would have to be as big as a good-sized portmanteau for a $7\frac{1}{2} \times 5$ camera; and, unless made exceedingly heavy—at least twice the weight of a complete $7\frac{1}{2} \times 5$ camera, dark slides and case complete—it would collapse. Secondly, as to the plates being half the thickness of those at present in the market: this is just possible, but the cost of such glass is enormous. Glass sheet is made by blowing it into cylinders, which are then slit down one side and rapidly flattened. If the cylinder be blown out to the thinness Mr. Harrison desires, the risk of bursting is so great that the manufacture is to all intents and purposes abandoned as impracticable. Besides, unless the thin glass be plate—still further increasing the cost—the risk of breakage of the resulting negative in printing is so great as to be practically prohibitory.

As to "the glaring—the vital—fault" of tourists' cameras wasting a minimum of ten and a maximum of twenty or more minutes in setting up, Mr. Harrison must have some extraordinarily prehistoric set of apparatus; for if there be one point more than another that has been studied by the makers it is this of rapidly setting up, which is, however, by no means of the vital importance that many amateurs think. The first essential in a tourist's camera is that it shall be one that a tourist can carry. For this sake alone it is absolutely essential that it shall pack up in a compact form, and, *cæteris paribus*, the preference will be given to one that is least complicated in its manipulation.

Now, judging from the tenor of the late Mr. Pritchard's remarks, the camera that would have suited him best would have been a plain box, serving both for camera and packing-case, to contain an inner cardboard box full of dark slides. His lens might have been mounted in a sliding tube, which would have given him all the focussing he required, and all could have been ready for use in a few seconds. The stand, if of a portable type, would, of course, require (say) one minute for setting up—not a very serious delay, and not to be reduced very materially by the employment of any non-folding stand. I can assure Mr. Harrison that there are plenty of tourists' cameras in the market with all the adjustments necessary for the very highest class of work, and with all the range of focus which he so rightly desires, that can be taken out of the case and set up for any length of focus in less than half-a-minute. The stand can be set up, lens in place, and focus adjusted within two minutes comfortably, without any hurrying; and, moreover, that these cameras are of such a type that they can be carried about ready set up on their stands with the greatest ease in case one should happen to be prowling about in search of instantaneous "shots."

It is, however, very questionable whether it is fair to expect a thoroughly-efficient, long-focus, portable camera to be capable of doing really high-class instantaneous work. For this I should prefer a perfectly rigid camera of not less than one and a-half time the length of the plate, without any adjustments whatever. As a shutter I consider that none are at all comparable to Edwards's rolling blind working close to the plate. If this were made permanently attached to the camera, it could easily be made so perfectly light tight as to allow of the camera being carried about ready for exposure with the lens uncapped. For focussing, the lens should be mounted on a sliding tube, which might have ascertained register marks for various distances. Two studs on the top of the camera would make a finder, while the focussing-cloth, attached permanently to the rear end of the camera, would effectually protect the dark slide. No case would be required and no setting up; nor focussing, after one had mastered the art of judging distance.

I take it that the main object of a tourist is rather to obtain good negatives than to expose a large number of plates. A gross of plates extra per month exposed is an average of nearly six per diem—probably a far greater average per fair photographic day, and means a very considerable amount of work in developing, coating, washing, and printing. I would rather expose fewer plates and take my time over the exposure. Well, even this fancy of exposing great numbers of plates very rapidly is provided for. There are changing-boxes in the market by which half-a-dozen or a dozen plates can be exposed in about twice or three times the number of seconds—well-made articles, too, that work without a hitch.

For my own part I abominate them. I like to carry a dozen plates with me, but I am very well contented if I can expose half of them in a day. My case holds four double dark slides—sufficient for any ordinary day's outing—and for special occasions I carry some extra dark slides in a separate case. The camera has great range of focus, and can be set up in a few seconds without the lens. The focussing-screen I have loose, and put in my pocket. I first of all choose my point of view, and then, having the camera set up without lens or focussing-screen use it as a view-meter, looking through the lens aperture and racking out the camera till the back frame exactly frames the view I want, as I find that in this way I can judge far better of the manner in which my picture composes than when reversed on the ground glass, or viewed without the frame. I then see by the marks I have made on the tail-board the exact focus of lens it will require to give just that picture, and choose from my lenses the one nearest to it.

My battery of lenses is very simple. It consists, first of all, of a rapid rectilinear of a little longer focus than the length of plate, which I never use with a large stop if I can help it. One lens of the combination gives me a very long-focus single lens. A few other single lenses of intermediate foci fit the same mount and work with the same stops and cap. The length of exposure required is readily calculated from the focus of the lens. I should mention that the rapid combination is remounted, the preposterously large hood taken off and replaced by one of the same diameter as the body of the lens, so that when the front lens is taken off the same cap fits the lens body. The back lens is also removable, so that the front lens can be used alone as a single lens with the stops behind it. It is also so mounted that it and the back lens—as, indeed, are the extra single lenses, too—can be used either in front of or behind the stops and fit the same cap or shutter. I have also a shorter-focus rectilinear working with the same cap or shutter for interiors, of the same length of focus as the length of plate, and which is about the shortest focus allowable.

It is, of course, necessary in some very confined situations to use a lens which includes a wider angle; and, although the perspective given by such a lens is absolutely true, it is so apparently unreal (because it is a wider angle than the eye is in the habit of grasping) that it should only be used in desperation as a very last resource.

The shutter I have adopted is the one originally introduced by Hunter and Sands, and consists simply of a leather band passing upwards and downwards over a roller in a little framework in front of the lens. This leather band has two diamond-shaped openings, which are pulled one over the other by a string attached to one end. Theoretically it is quite wrong to put it in front of a double combination. It should there cause unequal illumination. Practically it does nothing of the kind, for the simple reason that the lens itself gives unequal illumination if used with full aperture and made to work on its full-sized plate, but very equal illumination if stopped down and used on a smaller-sized plate. I rarely use it, though it possesses the inestimable advantage—counterbalancing every conceivable advantage of any more perfect shutter—of having the duration of exposure under perfect control at the moment of exposure; because it is very rarely I attempt subjects that cannot be done by hand exposure when I can partially shade the sky.

I hail with pleasure the practical form of bayonet-joint described by Mr. A. Pringle, and suggest that it would be still better with three studs instead of two; but, for all that, I do not think there is much chance of its being generally adopted. The trade, as I have before said, are very unwilling to adopt any new method of construction, involving, as it does in this case, the change of an entire system. Another, and far more serious, practical difficulty in the way of its general adoption will arise from the fact that it is a job which requires some degree of skill and attention on the part of the workman—a combination of qualities which seems every day to become rarer.

The high degree of finish which is attained in many branches of metal-work is principally confined to objects which are in great demand, when it becomes possible to so subdivide the various parts that an ordinary workman, by force of "pegging away" at the same thing week after week, becomes expert at it. Put the same workman to another job which is at first necessarily time-work and the cost of production is increased tenfold. The plain screw thread fitting tolerably well is within the reach of an ordinary brassfitter. The standard thread, so fondly imagined and so glibly talked about as desirable, is infinitely more difficult of attainment than is generally supposed. This will, to many, appear extraordinary; but, if they have any doubt of it, let them go to a real scientific instrument maker and inquire the price of a screw a couple of inches long and (say) a-quarter of an inch in diameter fit for micrometer measurements. I expect they will find that it would cost as much as a modest photographic outfit complete; and yet it is only an accurate standard screw.

Interchangeable parts are just possible, but only where the quantities are very great and the real standards of size readily accessible. The Microscopic Society tried to establish a standard thread for all objectives; but I frequently hear complaints that they are really not interchangeable. The attempt of the Photographic Society of Great Britain to introduce standard threads will, doubtless, bear fruit in time; but the trouble of getting and keeping to the true standard is so great, compared with ordinary approximation, that it will be years before anything like certainty is obtained with threads by different makers. It will be something gained if the Whitworth standards of so many threads to the inch are even attempted to be adopted.

When the Photographic Society of Great Britain decided upon their standard I at once sent to a reputed first-class tool maker's for a stock and dies, and at once, while the taps were quite new, made myself a plate of steel—afterwards hardened—as a standard. It had not been in use long before I found fault with the fit of the screws in their sockets, particularly when there was a considerable amount of thread in the nut. A careful examination of the stock and tap revealed a very appreciable difference in the pitch of the thread. Perfect screw-cutting apparatus, if it exist, is quite inaccessible to the average manufacturer. With the tools that are within his reach, the approximate perfection attained by a good workman is, to say the least, remarkable.

Mr. Harrison suggests that some arrangement should be made for instantly fixing the camera on the stand-head, and Mr. Pringle falls into the same error. A moment's reflection would have told them that a certain amount of rotation is absolutely necessary, and by general consent the central thumb-screw has been adopted as a simple, inexpensive, and wonderfully-efficient way of securing both rotation and firmness and security. The hole in the thumb-screw, for a string to tie a weight on, is "as old as the hills," and not a very good idea either, as it entails that very fumbling at a hole to which every one objects; and, in the very few cases where a weight is required, the end is far more easily obtained by making a slip-loop of the bight of the string and passing it over the screw-head on to the shank of the screw.

Mr. Harrison complains that the dark slides are too heavy. Lighter ones with the shutters of cardboard or thin metal to draw completely out have been in the market a long time. I myself have made no others for five or six years, and, moreover, the plates do not rattle about in them, while, still further, they do not slide into the back of the camera at all, but drop into a rebate breaking the light joint all round, so that all these requirements of his have been anticipated. Mr. Pringle condemns them—I can only suppose because he has never tried them. I, who have, would never willingly use a dark slide the shutter of which did not completely pull out; and can assure him that the "gimcrack affairs," as he terms them, are in every respect as thoroughly efficient as the highly-polished, brass-bound gewgaws. No one would dream of carrying dark slides about without some external protection from dust and light. A light cardboard box is amply sufficient if enough space be not provided in the camera case; while, as for being light tight, they can be handled in full sunshine as much as can ever be needed, and with perfect confidence that no harm will come to the plate, and, moreover, I have never had a failure with them which could in any way be traced to the dark slide. I do not think he could say as much for those with the folding shutters that do not draw out.

The level is another point which both Mr. Harrison and Mr. Pringle advocate without having thought it out, and whether in the circular or double form is equally unpractical—if for no other reason than the difficulty of placing it where it can be conveniently seen. A practical man would set himself to work to judge by the eye when his camera (or swing-back) was perpendicular, and, failing in his ability to do this correctly, would take the line of the building he is photographing as a guide, or simply hang his bunch of keys to a string and use it as a plumb bob.

A description of my tourist's camera will be found in THE BRITISH JOURNAL OF PHOTOGRAPHY of 2nd November, 1883, where the Editors do me the honour of remarking:—"We are inclined to believe that in the perfect tourist camera of the future, whenever the advent of that instrument occurs, will necessarily be found some of the features here described." GEORGE SMITH.

NOTES FROM THE NORTH.

"THE King is dead! Long live the King!" It is in the nature of things that the old must give place to the new, and yet it was with saddened feelings—a sadness shared by many old photographers present—that I recently saw the apparatus and appliances of the old and well-known firm of Ross and Pringle brought to the hammer. The firm, originally Ross and Thompson, was founded, I think, in 1847, and had for some time only two competitors in Scotland. It did much good and profitable work in the daguerreotype days, and was one of the first to make practical application of the beautiful—the troublesome—albumen process. At an early period of its history the firm received substantial recognition from royalty in addition to the appointment of photographers to Her Majesty. Mr. Ross's knowledge of art and his ability as an artist, at a time when amongst photographers such knowledge and ability were the exception and not the rule, were recognised far beyond the "three Kingdoms;" and his productions were largely, and often without his sanction, appropriated by many of the illustrated periodicals.

I visited the premises recently occupied by Messrs. Ross and Pringle a few days ago, and was much struck with the alterations the new lessee, Mr. Crooke, in accordance with his ideas of the exigencies of modern trade, has made. The spacious reception-rooms have been got up in the highest style of the decorator's art. The old studio, large enough for the work of earlier days, has been removed and one measuring about forty-five feet by fourteen feet erected in its stead, and furnished with a complete system of opaque and translucent blinds, on frames so arranged as to admit of any kind of lighting that artistic taste can suggest. Winter cold will be ameliorated by a perfect system of hot-water pipes, and summer heat rendered bearable by a satisfactory system of ventilation, under complete control by the operation of a single lever.

Mr. Crooke has shown a laudable desire for the comfort of his operators in constructing a dark room of about twenty by sixteen feet, with a window nearly five by three and a-half feet. On entering this room I was particularly struck with the bright, cheerful light that illuminated every corner; and my first idea was that it was intended for the sensitising of paper or filling frames. It was noon of a bright sunny day, *the window faced the south*, and was covered with two thicknesses of "canary medium;" and on no conceivable testimony short of actual ocular demonstration would I have believed that even a moderately-sensitive gelatino-bromide plate could have been developed without fog at a distance of only the breadth of the sink from the window. But I saw it done, and that, too, on a very rapid plate, and therefore mean in future to have faith in canary medium. Of course I hardly expect all my readers to believe what I most certainly doubted myself, and therefore have pleasure in saying that anyone who may be passing through Edinburgh should call on Mr. Crooke, who will be glad to let them see what he showed me.

By-the-bye, I wonder who makes the canary medium? There is room for improvement in the kind of paper employed. All that I have seen is of an irregular, mottled, or cloudy texture; and, as its power as a non-actinic medium is only equal to its most transparent parts, a paper of even texture would give still more light with the same protection. I have a strong belief that anyone who will lay aside prejudice and give the medium a fair trial will at once adopt it, and so a demand will be created that shall warrant the manufacture of a quality even better suited for photography. I should think a well-made paper of about 20 lbs. demy would answer admirably.

The Forestry Exhibition, after having been open some time, is now in a very complete state, and contains much that is specially interesting to photographers. I had hoped to be able to invite intending visitors to bring their cameras with them; but an application to the Secretary some time before the opening revealed the fact that Mr. Moffatt, with his usual zeal in the commercial aspect of his profession, had secured the exclusive right to photograph in the grounds and buildings, and, judging from the work he has already accomplished, it will turn out a successful speculation. In addition to a considerable amount of portrait work in an admirably-equipped studio, he already shows a large collection of excellent 12 x 10 pictures of the most interesting exhibits.

It seems strange that more of our local photographers have not taken advantage of the rare opportunity for advertising themselves that is afforded both outside and inside the grounds. The only advertisement outside is that of Messrs. A. and G. Taylor, who content themselves with a modest poster; and inside Mr. Marshall Wane stands alone, although a host in himself, with an elegantly fitted-up case, containing specimens in his best style, both in silver and carbon. Mr. Magnus Jackson, of Perth, who styles himself "Photographer to the Scottish Arboricultural Society," shows, in the court in which that Society's exhibits are placed, a large and fine collection of photographs of most of the celebrated trees in the country, and nearly all of these bear unmistakable evidence that he is not only a good photographer but an able artist.

Photography, as was to be expected, plays an important part in the exhibition, most of the countries having supplemented their actual exhibits by photographs, showing, better than any printed description could do, the various methods of cutting and transporting trees, wood-working machinery, &c. British Guiana is, perhaps, the largest exhibitor in this way, followed closely by Japan; but I was sorry to notice a large number of the prints exhibited by the latter getting into the "sere and yellow" stage.

Taking it all in all, photographers have no reason to feel ashamed of their connection with the exhibition, and I have no hesitation in saying that, both in point of quantity and quality, there is in photography alone sufficient material for spending a profitable day.

The explosion of a gas-bag in Drury-lane Theatre has done good in so far as it has elicited an interesting discussion on the question of lime light generally; but why there should have been a gas-bag there at all passes my comprehension. Scotchmen, as a rule, are slow to admit that, except in the trifling matter of climate, they are in anything behind any other country, but we know that England has bigger and better theatres, and especially more elaborate and perfect arrangements for scenic display; and yet it is a poor theatre indeed on this side of the border that has not long since discarded gas-bags in favour of the more convenient, more economical, and in every sense more perfect, arrangement of gas-tanks. Some dozen years ago—the exact date I cannot find, as I have not at present access to my file of the Journal—I published a description of a set of tanks that were then fitted up in our west-end theatre. I had subsequently an opportunity of watching the nightly working of a similar pair during a long run of a pantomime that drew upon their resources to the utmost extent, during which time from twenty to fifty burners were worked without a single hitch. Those were made after the pattern of a set in an English theatre, and until the Drury-lane disaster I had fondly believed that the inconvenient, expensive, and in unskilled hands dangerous, bags had long been relegated to itinerant exhibitors. That they will, by-and-by, be altogether things of the past I have not a doubt; but it will not be till English makers discard the heavy masses of iron of which their gas-bottle at present consists, and adopt the large, light, and at the same time sufficiently-strong, cylinder so generally used in America.

John Nicol, Ph.D.

PHOTOGRAPHY IN BELGIUM.

[From Our Special Correspondent.]

Brussels, September 1, 1884.

As regards the facilities given by the Belgian government for popular education in photography, and for original experimental research by photographic experts, M. Léonce Rommelaere informs me that the use of the chemical laboratory in the Industrial Museum at Brussels is open to foreigners as well as to Belgian subjects, under precisely the same conditions to both. Supposing, however, that a foreign photographer wished to make use of the costly microscope, or the superb spectroscope with its train of six Iceland spar prisms for photographing the ultra-violet rays, or other exceptional apparatus, the authorities would necessarily only permit the use of these to foreign experimentalists with whom they had some kind of acquaintance. These instruments are not in the chemical laboratory, but in a room below. Where can an English photographer apply in London to obtain similar facilities from the government? Considering the number of skilled scientific photographers in England, there is no doubt that such facilities would do much to promote photography as a science. There is also no doubt that those who contribute the funds by which public scientific establishments are upheld have the right, in most cases, of participating directly instead of indirectly in their use; this is done in Belgium and some other free European countries.

M. Rommelaere, as stated in my last, accompanied me over the rooms of the department for the free teaching of engineering and mechanical drawing. He, however, is not the professor who gives education in these two subjects. In my last, I too hastily jumped to the conclusion that it was himself. He teaches chemistry, physics, and photography.

Last Sunday the national demonstration to request King Leopold not to sign the new school law took place. Antwerp alone ran fifteen special trains to carry processionists to Brussels; and from other towns, large and small, vast numbers of persons came. I watched the procession for half-an-hour crossing the Rue Royale, and then I went elsewhere; when I returned to the same spot two hours later the end of the procession had but just reached it. The clerical party holds a counter demonstration next Sunday; their followers live chiefly in the rural districts. One of their official circulars tells their followers that whoever does not come will be disowned by his superiors and friends; another tells them that their railway fares will be paid. One of the newspapers says that dinners will also be provided for them.

A statement has been published in England that little in the way of good landscape photography is to be seen in the shop windows of Brussels. After my prolonged stay here I do not remember to have seen a single photograph, good or bad, of a Belgian landscape. There are plenty of architectural photographs—some good, the majority of indifferent quality, and all, or nearly all, of them without natural clouds. The new Palace of Justice in Brussels is one of the finest modern buildings in the world. Many persons here believe that there is no modern building anywhere to equal it. Probably they may be right. Other modern buildings may have cost more money, but I have never seen one which impressed me more with a sense of magnificence of architectural effect. This is stated only with respect to modern secular buildings; it is not possible to draw a comparison between a building of this kind and the cathedral, for instance, of Rheims, or Chartres, or Milan. The new Palace of Justice in London is as nothing for architectural effect when compared with that of Brussels. The photographs of the latter, so far as I have seen them, fail to do it justice. Most of them spoil it by the use of wide-angle lenses. Some of the photographs of it are not sharp all over, none that I have seen give it with natural clouds above, and probably the work yet remains for some one to execute with efficiency. The tones of the architectural photographs in Brussels are not usually rich ones. There is room for general improvement in architectural photography, and at present the field of local landscape photography seems to be wholly unworked.

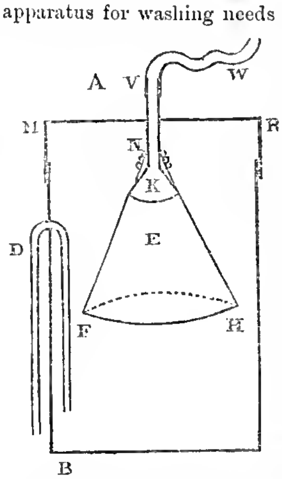
As for photographic portraiture in Brussels it is excellent. The proportion of good to bad portraits on public view in the city is, I think, larger than in most towns.

English photographic apparatus, lenses, and bromo-gelatine plates are largely used at Brussels, and well spoken of by those who employ them. It is evident that some manufacturers of these things have found a good and friendly market in Belgium.

Brussels is the nearest foreign city to London in which a strong photographic society is established, and in which various branches of photography are utilised in Government departments on the spot. The large city of Antwerp contains no photographic society, but Brussels is reached from it in one hour. If an International Congress of Photographers could be inaugurated, Antwerp, in May next year, would be the place and time for it, since the Antwerp International Exhibition will then be opened. The International Congress on Photographic Standards is to be held there in May, but this is limited in its work by its title and otherwise.

Messrs. Géruzet Brothers at Brussels, photographers to the Queen of the Belgians, have been established for thirty years. The business was founded by their father. For many years past Messrs. Géruzet have not turned out a photograph liable to fade, all their printing, even the smallest, being done by the carbon process.

Messrs. Albert and Alfred Géruzet make their own emulsion, and their apparatus for washing needs but to be attached to a tap which allows



running water to pass, and the emulsion is washed in the dark without need of further attention. The washing vessel is a cylindrical one of zinc, A B, about two feet high by sixteen inches in diameter. M R is the lid, partly let down into its place; a zinc pipe, K V, is soldered into the lid, and expands at the end K into a perforated rose-discharger for water. The bag E, containing the emulsion, is tied by its neck round this pipe at N; the bottom of the bag is distended by means of a ring of silver wire, F H, inside. The syphon, D, soldered into the side of the vessel, has its longest leg outside. The action of this is obvious. The whole apparatus is connected with the water tap by means of the caoutchouc tube W. The water washes the emulsion and is changed every time it rises above the level D, since the syphon then automatically discharges it; the vessel now fills again, is again emptied, and so on, without any attention from the operator.

The first time I entered the studio of Messrs. Géruzet a surprise awaited me. I found Mr. Albert photographing a row of human bodies with no heads. With a second glance the excitement subsided for the projecting feet of the corpses were of wood, and each had three; the ghastly sitters, or standers rather, were evidently dummies. The President of the Belgian Association of Photographers having previously told me that Géruzet Brothers were among the cleverest photographers in Brussels, it then struck me that they had hit upon the plan of photographing elegantly-dressed bodies, and afterwards putting heads of sitters upon them by double printing, so that a poor person who could not afford a rich costume, or stand steadily in unaccustomed splendour, could be furnished with a special body and dress to order at one fell stroke. This, however, was not the true explanation. A fashionable draper had sent his new costumes to be photographed, dummies and all. Two hours later I met all these headless bodies in the street with white sheets over them, as the assistants were carrying them back to the shop of their owner. The uncanny procession would have made a good photograph.

When coating very large plates with collodion Messrs. Géruzet use no holders, but rest the middle of the plate upon a kind of tall, substantial, wooden mushroom fixed in the middle of the sink. By means of this central rest the hand which holds the plate at one corner can easily tilt it in any direction. As the top of the "mushroom" is liable sometimes to get splashed, the plate is not allowed to rest directly upon it. A strip of thick, clean gutta-percha, kept for this purpose only, is placed temporarily between the rest and the plate; because of this protection, the plate is not liable to carry dirt from the rest to the silver bath.

Messrs. Géruzet are the inventors of an electrical machine for retouching, which has, I believe, already been publicly noticed in England. From external appearance it might be thought to be made on the principle of the Edison electrical pen, but examination proves it to be upon another principle altogether. A small electro-magnet sets its armature into high-speed vibration by means of the usual make-and-break contact; thus a tremor is given to the several ounces of metal forming the electro-magnet and armature. This tremor is softened by passage along a spiral wire so closely wound as to form a kind of short flexible tube, the other end of which tube carries the metallic holder of the pencil. Thus the pencil is in a state of incessant tremor, and does its own stippling. I tried the apparatus on a negative, and would much rather use it than peck or scratch away at the negative by hand. The metal work just described is, of course, heavy; but this difficulty is overcome by mounting it on a counterbalancing arrangement.

In Messrs. Géruzet's largest copying work the interior of a dark room is used as a copying camera; the negative is outside, and the light from the zenith is sent through it by a mirror at an angle of forty-five degrees. No cap is used to the lens, but a sheet of yellow glass, the light through which is sometimes useful. On the wet collodion plates of the size in use during my visit the time of exposure in enlarging was twenty minutes.

The operations of carbon printing being carried on at the top of the premises, with a developing-room abounding in steam and warm water, the floor of the developing-room is of sheet lead to protect the ceilings below. The workmen wear French wooden *sabots* to save their boots in this constantly-sloppy region—a plan which may be worth consideration upon the other side of the Channel.

In carbon printing, Messrs. Géruzet perform the development on sheets of opal glass, and on the same sheet develope pictures from negatives of slightly varying degrees of intensity. They bring the pictures all up alike in the long run. If one refuses to come up like its neighbours, even after the application of warmer water, they add some ammonia to the water, and thus produce the desired result. It is best to develope slowly at a moderate temperature, and then to deal separately with any obstinate case.

Messrs. Géruzet are just trying a new style of portrait, in which the sitters appear with real landscapes in the background, so as to get rid of the unnatural look of most of those which are artificial. They are at present engaged in perfecting their system, but they showed me a portrait of the Countess of Flanders walking through a wooded path. The effect was most natural, and left nothing to be desired. A compound negative is first made, from which any number of subsequent copies can be produced. A difficulty is, that at first the human forms appear to be floating in the air, like figures of living things stuck upon a screen; their feet have to be fixed upon the ground by skilful retouching.

Messrs. Géruzet have some large medallions in relief, upon copper; they are some sixeen inches square, and exquisite specimens of artistic work, produced by a gelatine relief and photo-galvanic process. This process is the property of a Parisian firm, and only last week Messrs. Géruzet bought the exclusive right to use it in Brussels. The copies from the negatives are made in Paris.

ON THEORISING.

There exists among some people an unfortunate proneness to unduly expatiate on infinitesimal portions of detail, to make all sorts of chemical and mechanical experiments, and then to favour the perspiring portion of humanity with a minute registration of how the unexpected did not happen or how certain inadvertencies did not produce the anticipated failures. Now, those of us who have neither time nor inclination to manipulate with the dark-room door ajar just to see what it will do, nor to keep our developers like our wine, and then "try a plate," will naturally ask what these operations have to do with art. Our concern is to stamp the imprint of genius upon the best materials the market supplies. If we are fortunate enough to discover we have no genius then there is no obvious necessity to publish the evidences of our destitution!

The painter does not discourse on the particular excellence of a special make of colours; he does not wax eloquent on the effects he produces by certain combinations of these colours; neither does he read a paper on the merits of red or brown sable. He appeals to us by his method of utilising the appliances at his command, and by the effect which his conception produces on our minds do we pronounce him a skilful man. Being neither a colour nor a brush maker he does not stoop to those mechanical details concerning the tools of his art. His part is simply to shape his means to an artistic ending. In like manner the photographer, not being a plate or paper maker, has quite enough before him in his short life if he can imprint an artistic individuality upon each one of his productions. If he cannot do this—if his skill be not sufficient to become marked in his pictures—he is simply a manipulator of chemicals—a mediocrity, or one who has mistaken his vocation.

It may be urged that the photographer is more dependent on his materials than the painter; that certain brands do not produce in his hands the inception of his brain. The remedy is obvious; and it will be sufficient for him if he discard this evil in his day and leave to the authors of his mischief the task of fighting it out amongst themselves. The excellence which should be the aim of every photographer cannot resolve itself into a modification of any existing formula. It will not depend on diaphragms being denoted by one set of numbers or another. It is not an end which can be attained by spring shutters or drop shutters. A plate may register 5 or 50 on the sensitometer, and the technical nicety may be highly appreciated; but it will certainly not in any way conduce to the production of a work of art.

Argan in the "Hypochondriac" is in tribulation, because he has forgotten how many grains of salt he should eat with an egg, and whether in taking exercise in his chamber his doctor meant him to walk the length or the breadth of the room for a certain number of times. But it is not matter for much speculation how far this minute attention to detail will affect his general health, any more than it would concern the painter to know if the hairs in his brushes were to be computed by the odd or by the even numbers. His mind soars above such atoms of knowledge; his concern is with the production of the beautiful, which cannot die.

"Of course," asks the physician of the "Hypochondriac"—"Purgon has ordered you nothing but roast?" "Indeed, no," replies the unfortunate man, "I am to have all my joints boiled." "Just so; boiled or roast, roast or boiled, it is all the same thing, and you could not be in better hands!" Follow this thought; and so that the result be a work of art, what matters (not being plate-makers) if the particular emulsion was boiled or baked. Our concern is with the picture, not with the technicalities or the theories of the tradespeople who supplied the materials used in the production of the picture. The brains of the artist seek higher contemplation than the poring over of so much humdrum detail; and as we should scarcely attempt the composition of an epic poem amid the din of a boiler shop, so we should not seek the ideal of beauty by an elaborate computation of the number of grains of chemicals used in bringing our mental conception to view.

Mahlstick.

SOME REMARKS SUPPLEMENTARY TO THE DIRECTIONS FOR THE USE OF HUSNIK'S PHOTOGRAPHIC TRANSFER PAPER.*

All the manipulations have now been described to which Husnik's photographic transfer paper should be subjected in order to be able to use it with ease and certainty; but there are some small establishments where reproductions are made which do not possess a really good satin press, so I thought it might be useful if I were to explain how the tissue might be rendered literally as smooth as a sheet of glass, without being burnished.

This operation consists merely in allowing the sensitised tissue to dry upon a sheet of plate glass rubbed with tallow, and then drawing it off when dry. The surface of the tissue then takes on the polish of the glass, and furnishes finer results than can be secured by any other method; indeed, even the asphalte process itself cannot compare with it, owing to the always imperfect contact of the zinc plate with the negative. This mode of treating tissues is certainly known already, but it has hitherto usually been used only for gelatine tissues developed by roller—a very difficult operation.

Here a sponge may also be used for developing, but it is well to commence the development by first removing the superfluous colour with a velvet pad, and not to begin to develope with the sponge until the white lights are already clean.

Detailed Description of this Operation.

Rub with beef tallow a clean sheet of plate glass a little larger than the sheet of tissue to be glazed, sprinkle the plate with stone alum, and then rub all off again with *papier Joseph*. Now pour the chrome bath into a clean dish, and lay the glass plate in the solution.

Next moisten the prepared sheet as usual, and after a minute or so lay it gelatine side downwards (in order to guard against air-bubbles), and then raise it to the perpendicular along with the sheet of plate glass. Having allowed the moisture to drain off for a minute or two, lay the glass, tissue bearing side uppermost, upon a table previously covered with blotting-paper; put a couple of sheets of blotting-paper above the tissue, and then a sheet of common paper above that again. Now press out all the moisture with a squeegee, beginning at the middle and pressing towards the edges. Then dry the back of the tissue as well as possible with blotting-paper, and set up the glass and tissue in the dark to dry.

Next day the tissue will be dry and may easily be stripped off, when it will retain the polish of the glass and the *dimensions of the tissue when wet*. This last is a very important matter when things have to be copied so as to retain a certain size. It is universally known that paper expands, when wet, only in one direction; and, as the tissue is exposed in a dry state but transferred in the wet condition, it is evident

* Concluded from page 490.

that all pictures must be larger in one direction than the negative from which they were printed. It is further evident that this distortion must always occur in the direction in which the paper expands when wet. This mirror-smooth paper having been fixed to the glass while wet, and having remained so until it became dry, has retained almost exactly the dimensions of the wet paper, and, therefore, will not expand any more when again laid in water.

After exposure the prepared paper should be blackened, by means of a velvet roller, with common transfer colour containing eight parts of wax, or with Husnik's transfer colour. The colour should be thinned with a little oil of rectified turpentine. The print having been laid upon a level plate (a zinc plate), one side being tucked under in order to afford a better hold, the upper surface is rolled very lightly with the colour, so that the drawing shines through. The colour should not be spread by means of cotton wool in this case, as, owing to the mirror-like smoothness of the upper surface, the colour would never be equally distributed.

After a lapse of ten minutes place the print in water and develope in half-an-hour—first with a pad covered with velvet, and afterwards with a sponge. The further manipulation is the same as that already described. J. Husnik.

—*Notizen.*

WHERE TO GO WITH THE CAMERA.

[It is hoped that this series of articles will be continued at regular and frequent intervals during the vacation months, and we shall be glad to receive contributions to the series from any friends able to treat of new and interesting ground.]

THE ENVIRONS OF CHELTENHAM.

With this charming town as headquarters, and where accommodation of every kind is available, I purpose acting as a *cicerone* to the photographer eager for good ground to pitch his camera on, promising him, to start with, endless *matériel* of the loveliest kind.

Cheltenham itself — with its fine transformation - scene - looking promenade, its Lansdowne and Pittville—is already so well known that nothing is left to be told but what has already been fully and ably described. Still, it may be said that a good few plates might pleasurably be used in the rendering of some of the pet parts of the town proper. Topographically speaking, westward of Cheltenham lies the Vale of Gloucester, while stretches of the Cotswold form some sort of crude crescent round the town. Now, it is precisely on and about these hills that the bulk of the views, scenes, &c., to which I am about to refer are met.

On starting eastwise—which may be as good a way as any—by the Prestbury Road, the pretty village of Prestbury is reached, and here the first halt may well be made. The church, *sui generis*, is good, and the surrounding locality excellent. One might easily contrive to occupy one's time with the camera until the carrier passes in the afternoon, and, having secured a seat, proceed to the "Rising Sun," which is some couple of miles further. Part of the way is through a delightful country under the beneficent shade of a wood formed of fine tall trees. If it be thought desirable to secure these it is needless to think of the carrier, but simply wend one's way thither, and on *via* Southam, where some good farmhouses and quaint barns are to be met.

Shortly after leaving Southam the ascent up to the "Rising Sun" begins. Once at this inn one may profitably put up, for the district immediately round is very good. Situated on what is called "Cleeve Hill," the tourist meets with rugged "bits," panoramic views, and pretty lanes going down the village of Cleeve, which lies some distance off in the valley, and where good things are likewise to be secured. This district exhausted, one may proceed three miles further, to the little town of Winchcombe, close to which is Sudeley Castle. Putting up for the night would be advisable in Winchcombe, and the next morning you would find "food" in sufficiency for the camera. It is needless to say that all information respecting Sudeley Castle will be easily obtained in the locality.

Photographic operations over in and about Winchcombe, you can return by omnibus to Cheltenham, whence, after another night's rest, a start may now be made for the Old Reservoir, *via* Battledown, and then on to Agg's Hill, with a delightful road all the way from Battledown right to the top of the hill, where very fine views are offered to the gaze. Here a vast extent of country lies before the tourist. The Vale of Gloucester, Gloucester itself in the distance, and right down to the Bristol Channel may be seen on a clear day. From this plateau (on Agg's Hill) I, about a month ago, saw Cheltenham bathed in an Italian atmosphere, looking as fine as anything I ever saw—the houses beaming in soft, golden tones in the midst of the finest conceivable aërial atmosphere. The effect was simply splendid, and I would have wished it to remain so for ever. By the way, how lovely the colouring and atmosphere have been this summer! It reminded me more of the rich bloom I saw throughout the Scotch atmosphere in the vicinity of Ben Venue and Ben Lomond than anything else. How very unfortunate it is that the perfections of atmosphere are denied to photography! How pale and insignificant—how very tame—is photographic atmospheric rendering! How very often, too, what was so charming about the distance is seen to flash out and instantly disappear under the action of the developer to the plate! But to return to Agg's Hill: though much of the beauty of the views thence must perforce be lost to the photographer, still there is much that may be done and that well deserves attention. Next to this, on the higher road parallel to Battledown proper, the camera will find a considerable amount of occupation. The evening or early morning time would be best for it, even though exposure should have to be increased. To make up for this, vast shadows will then cover the ground. Untold depth and richness, with sparkling peeps through the foliage, amply repay additional length of exposure.

There is a village close by where I have spent most pleasant hours busily limning pictures; that is, Charlton and its suburb, Spring-Bottom, the latter of which furnished Mr. Baynham Jones with one of his most felicitous pictures, *Spring-Bottom Bridge*. Mr. G. S. Penny, likewise, did excellent work in this identical village, and still left ample room for others to follow. On strolling along it is amazing the number of things pictorial one meets, and the variety offered in this one village alone. Then through Charlton passes an offshoot of the ubiquitous London road, following which one comes on the site of the New Reservoir, half-a-mile further than which, looking back towards Cheltenham, is seen one of the finest stretches, or fragments, of the Cotswold I know of. It offers magnitude, variety, and great beauty, and is especially fine as the afternoon is wearing off; but then the sun being about dead against one, reproduction by photographic means has of necessity to take place earlier in the day. This individual spot is some four miles and a-half from the town clock.

If wishful for a really-fine mill, and distance be no object (four and a-half miles further), I would advise proceeding as far as Andoversford, now accessible by rail; and, close to the mill, the waters which feed it are nice, and, with their surroundings, will keep the tourist busy for some time. The spring about here, with its grassy bank and umbrage, is delightful during an afternoon, and forms excellent ground for a picnic party.

Till this time progress has been from due east on to the south, and between these points still lies a spot usually resorted to by visitors to Cheltenham—that is, the Seven Springs. With this place, however, I was much disappointed when I went, but much liked parts of the road going there, as one passes wild scenery much to my taste. Next to the Seven Springs, southwards, comes Leckhampton. On and about this hill an entire day may well be spent; and there will be no lack of variety either, the hill-side being here wild and rugged, then covered with firs, every now and then reminding one of fragments of Switzerland. I would advise beginning early in the morning at the foot of the hill. I have seen this individual part absolutely charming under a semi-haze, the villas and cottages coming out softly against the hill, and masses of trees hurling down rich shadows, thereby giving both variety and relief to the scene. A little higher up, if one suddenly turns a semicircle so as to face the road from Cheltenham, we again get a delightful view composed of the villas and houses with their surroundings, and an excellent picture may be secured.

Next, one might plunge into the wood and, peeping out from between the trees, take the foreshortenings of the hill side, the varied vistas, the clusters of trees resting on the undulating ground. As you wander about you are sure to come upon Leckhampton, its church and village. They are enticing, and well worth spending a few plates on. If not objecting to a little climbing, you might now take the road leading to the top of the hill and, looking to the right as you ascend, watch the magnificent view of the valley, out of which, twenty miles off, the Malvern hills are seen to rise; while more immediately close to you the ground, with its varied slopes, is most attractive and replete with pictorial materials. Then to the left, as you pass, you come on seemingly a wild superstructure of stones detached from the quarried side. This natural geological freak is called "The Devil's Chimney," and is notorious to all under that cognomen, innocent as it is of any connection with the evil spirit. Just before reaching the *plateau*, look at the fine hill side to your right, and the artistically-situated house called by some "the Folly." Pause here and, while gazing on the fine view, hark to the lowing of the cattle, the bleating of the sheep, the bluster of the bantams—is it not all truly delightful? And how replete with truly artistic material of every kind! But the *plateau* or hill top is now at hand. Pack up the camera and simply feed on the invigorating air and vast horizon. The dwellings of men seem small from here; horses and cattle are but specks, and men themselves are scarcely visible. Yet it is but a poor elevation compared with the titanic heights of India. Roam about the *plateau*, following the capricious indentations of the bluff, and quietly admire the vastness and loveliness of nature in this fine panorama.

Having refreshed yourself with another night's rest at your Cheltenham headquarters, the dark slides once more replenished, and partaken of a substantial breakfast, another spot now awaits your skill and energy. This spot, being six miles off, is probably best reached with a conveyance, the coachman of which will not be sorry on finding it to be Birdlip, though it is up hill a good part of the way. The first portion of the road will be your old friend of the previous day—the ascent up Leckhampton hill. Once close to "the Folly," however, you will branch off to the right toward's Cooper's Hill, a nice view of which is got as you walk while the vehicle is making its way up the incline. By the time you have "taken stock" of Cooper's Hill, from this favourable vantage ground, the conveyance is ready awaiting your convenience to resume your seat; and now whip away right to the village of Birdlip, the approaches to which, by the road just followed, give but little indication of the scenery in store for you.

It may be that a glass of milk and a biscuit or two would here prove acceptable, unless, having made a scanty meal early in the morning, you feel more ready for a *déjeuner à la fourchette;* if so, the means to indulge such desire are at hand. Whichever you elect, the Birdlip woods next await you. As you enter these by the village entrance, some fifty yards ahead, a vast clearing is manifest. As you open out upon it, looking to the left, I think you will admit the headland is well worth depicting; but resort should be had to a long-focus lens, otherwise the lines will be so depressed as to deprive the view of its character and consequent charm. The same kind of lens is advisable for the fine wooded promontory or hill to the left, ending about the little lake, which is, I think, the reservoir that supplies the city of Gloucester with water. Practically you may now think yourself in the heart of charming sylvan scenery; but one has to pick and choose, for some of it is but poor stuff—tall, slender trees, and a great deal of inferior beeches. If, however, you are a good walker, pass right through the more immediate rubbish and you will meet with much better and more picturesque timber. The thing is to get to the very heart of the wood, and on what I have termed the "promontory." It will not take long ere you perceive that there is much to do in this locality, and that valuable studies are here to be obtained in plenty. In parts, too, will be found splendid foreground material—burdock, thistle, in fact all that the painter seeks to enrich the foreground of his pictures with. There are many spots where this foreground material comes in appropriately along with pictures otherwise complete in these woods. If provided with a good field-glass so much the better, as you will be able more fully to enjoy your trip or stay, should you elect to stop for some days in Birdlip. The only difficulty in the way at times is to find sleeping accommodation, as the place gets very full in the season.

This spot exhausted, there is Painswick, three miles further on; and here again the country is very fine—replete, in fact, with good pictorial *matériel.* When ready to return to headquarters, I would strongly advise returning by the lower road, which skirts the wood, and through Shurdington, where again the camera might be brought into requisition, and finally back to Cheltenham. This individual drive, morning or evening, is very fine; and, if in the evening, glorious effects of sunset may at times be seen, sending a rich gloss through the foliage below, and, also, when on the open covering and the distant Malvern Hills, with an exquisite mantle of purple, while the golden-fringed clouds reflect the rich lustre of the setting sun. At these times the harmony pervading sky and landscape is pleasing to a degree. The colouring is now dramatic, then soft in the extreme, perhaps horizontal strata top the horizon, or portentous masses of cumulus cast long, impressive shadows over space and ground, offering a grand contrast to the rich, metallic light of the declining orb, as this light diffuses itself through the "peerable" space, and here and there in gaps in the landscape, lending a wondrous charm and mystery to the scene. The sound of a church bell in the valley at this hour is apt to remind one of the *angelus*, still common in some countries; and almost unconsciously the mind may be led to dwell on with a feeling of respect and gratitude, while absently gazing on the sublime scene.

Half-an-hour or so later finds you again in Cheltenham, with the whole valley abaft still unexplored; with Gloucester only a-quarter of an hour's distance by either Great Western or Midland—Gloucester, with its fine cathedral and grand, massive columns and fine tower; Gloucester, with some of the quaintest and narrowest streets of any I have seen, including those of old Paris—of the Paris of forty years ago. Then, in Gloucester docks, occasionally good shipping is seen, and groups of crafts of a picturesque character, such as have happily been depicted in his leisure hours by Mr. Penny. Finally: the upper end of the valley about Cheltenham is replete with pretty roads and lanes far too numerous to be enumerated here, and villages such as Swindon, &c., &c. In fact, endless *matériel* still abound in the immediate vicinity for an earnest toiler and genuine lover of nature.

A. F. GENLAIN.

FOREIGN NOTES AND NEWS.

HERR ANDERS' PRUSSIATE OF POTASH "BLUE" INTENSIFIER.—PROFESSOR VOGEL'S METHOD OF PURIFYING GELATINE FOR EMULSIONISING.

HERR ANDERS, of Dresden, says in the *Mittheilungen* that, in consequence of the well-known disadvantage of intensification with cyanide of mercury—namely, that the negatives sooner or later become darkened to yellow, and furnish in consequence first very powerful lights and, at last, prints that no longer come up to the desired standard—he has tried another method which also produces coloured negatives; but in this case the colour is blue or violet. This method of intensification is very easily manipulated, and the process has to be carried out by subdued light, as bright daylight decomposes the fluids. Take the negative to be intensified and wash it well after fixing, or the already-dry negative, and rinse it well again; then coat it with the intensifying fluid, or lay it in a bath containing some of the same. A porcelain dish is best, as it allows the progress of the intensification to be watched. The negative is at once converted into a "blue" picture, in which the high lights remain white, while the half-tones shade gradually off into a blue, more or less decided in tint according to the length of time the plate is left in the fluid. The fluid may be made of any desired weakness by dilution with water. It is principally intended for the intensificaton of under-exposed plates, in which it brings out with great distinctness previously invisible details. If it be desired to convert a blue negative into a violet or black one, the object is attained by simply laying the blue negative in a very dilute (1 : 100) solution of ammonia of 0·910, in which the blue negative is in a few minutes converted into a bluish-black, the change of tone beginning almost instantaneously. After being removed the plate must be carefully washed. It is noticeable that we are only told how the intensifier acts, but get no specific information as to what the intensifier is actually composed of, nor its proportions, further than that it is a mixture of red prussiate of potash with a ferrous oxide. It is said that Herr Anders has applied for a patent for this intensifier, presumably in Germany. He sent a "blue" negative to the Berlin Association for the Cultivation of Photography; but it was unaccompanied by a print. If the negative look very promising, perhaps Dr. Vogel will try a print from it and report thereupon.

The latter gentleman writes to the *Mittheilungen* as follows anent a simple and reliable means of purifying gelatine for emulsionising:—

"Pains have been taken, since the use of the emulsion processes became so widespread, to furnish suitable gelatines for them; yet there are still a good many kinds in the market which do not give good results with the cooking process, and still less so by the ammonia process—that is to say, their use is accompanied on the one hand by fog, and on the other by insensitiveness. I have had to contend a great deal with this difficulty, and have had to throw many pounds of gelatine and many more of emulsion away before I found a simple, sure, and reliable method of purifying gelatine. I have now used it for more than a year, and can recommend it for use with gelatines that would otherwise furnish absolutely no usable emulsion at all. The need for such a remedy is best proved by the fact that the Berlin Photographic Society has offered a prize for a good one, which no one has as yet merited. The method is simple:—Soak the doubtful gelatine in water (running water will often do, but distilled water is best), let it stand eight minutes, and then pour off the water. Repeat this seven or eight times, after which the gelatine should be quite clean and may be confidently used for emulsionising. I usually weigh out the quantity of gelatine required for a batch of emulsion, and after subjecting it to the washing process let the water drip and then melt it. I then measure the melted mass, and use one-quarter of it to emulsionise with, and add the other three-quarters after cooking. Very bad gelatine can be worked up best immediately after washing. At anyrate it is not advisable to let it stand long after washing. My experience is that a gelatine of that sort which was used immediately gave a good emulsion, but if left to stand twenty-four hours traces of decomposition had already begun to show. The gelatine tests I published some years ago should convince anyone that the washing process is really effective:—Prepare an ammoniacal silver solution by adding a 1 : 10 silver solution to ammonia until the precipitate formed at first has become redissolved; then mix some of the gelatine to be tested, after swelling it in water and melting it, with an equal quantity of the silver solution, and heat the mixture. If the mixture become brown or even yellow, the gelatine is not to be recommended. Now in every case in which gelatine washed as above described was tested in this manner it proved pure (clean), and with every sample so treated, without exception, a good emulsion was obtained."

RECENT PATENT.

APPLICATION FOR PATENT.

No. 11,803.—"Washing Trough for Photographic Negatives." F. BISHOP.—*Dated August* 30, 1884.

A NEW OR IMPROVED PHOTOGRAPH AND PICTURE STAND.

Communicated by THEODOR MÜNCH, Vienna.

THE stand is intended for the reception of photographs, lithographs, prints, drawings, pictures, or any other flat object, and differs from other similar apparatus principally by enabling the objects to be seen at the same time from different sides.

The photographs, drawings, &c., are placed one behind the other, slantingly or vertically.

In both cases the apparatus consists of a stand and a number of picture-holders or frames. The stand is made of brass, tin, or any other convenient metal, and rests on feet of any angular or any other shape that may be desired, with crosspieces answering to the shape. The picture-holders or frames may also be made of brass, tin, or any other metal, or of hard wood; and each frame may be divided into two or more compartments, each to contain a picture. On each side of the frame knobs or screws are provided, acting as horizontal axles on which the frames hang and turn.

[Certain drawings accompany this specification which we do not reproduce, and the claim is based on the foregoing.]

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
September 9 ..	Bolton Club	The Studio, Chancery-lane.
,, 10 ..	Bury	Temperance Hall.
,, 10 ..	Photographic Club	Anderton's Hotel, Fleet-street.
,, 11 ..	London and Provincial	Masons' Hall, Basinghall-street.
,, 11 ..	Manchester	Manchester Technical School.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on the 28th ult., the chair was occupied by Mr. W. M. Ashman.

A Member showed some gelatine negatives taken about three years since, which, he thought, had become dense with time. No intensifying process had been employed, but the plates were merely developed with alkaline pyro.

Mr. W. E. Debenham said that when it was necessary to look over old collodion negatives he found them very dense. The plates were not originally too intense, but had been of proper printing density at the time they were taken. His practice had been to develope with iron, and intensify with pyro. and silver after fixing.

The Chairman inquired whether the effect noticed was not due to different methods of printing.

Mr. Debenham thought not, and that the strong silver baths in use formerly would give, if anything, more powerful prints than those obtained under the conditions in vogue at the present time.

A Member, with respect to modes of intensifying, said that for many years Blanquart-Evrard, of Lille, employed the method of obtaining intensity by exposing the developed plate, after washing and before fixing, to daylight. Ten minutes sufficed to darken the image sensibly. He would put a query—"Was the change in this case due to an alteration of colour, or to a change in the agglomeration of the molecules forming the image?"

The Chairman had for many years employed the method referred to for obtaining intensity with collodion negatives. He had also, when the plate had been much under-exposed, adopted another method—that of immersion in bichloride of mercury as soon as the developer was well washed out; the plate was then printed from without being fixed.

Mr. J. B. B. Wellington showed a combined changing-box and dark slide. In this arragement each plate was contained in a carrier of tin plate. The top of this carrier had a slot in it which was taken into by a spring catch when the body of the box was drawn out, and on sliding the body back the plate was forced into a fresh position at the back of the others. By this contrivance the length of the back or changing-box was kept within moderate limits, and was not much greater than that of the plate itself.

Mr. F. W. Hart exhibited a flap shutter with pneumatic release. The shutter was furnished with a stop by which the rising of the flap could be limited to a certain height as desired, and so it would act as a sky-shade. There was also an arrangement by which the flap would work up and down instantaneously with one pressure of the pneumatic ball, or it might be kept open as long as desired, and would discend only when the pressure upon the ball was removed.

Mr. A. Haddon, referring to a question that had been put at the previous meeting, showed a piece of silver wire net and the frame upon which it was made. Anyone requiring such an article could manufacture it for himself.

A Member suggested for the purpose intended—that of dividing emulsion—the use of a piece of tinned wire gauze as sold in the shops for putting tea into when making the infusion. The piston employed would then have to be rounded at the end to match the shape of the strainer.

MANCHESTER PHOTOGRAPHIC SOCIETY.

[Our readers may have perceived that the reports of the ordinary meetings of this Society for April and May last have remained in abeyance since those periods. From a conversation we have had with the Hon. Secretary we have been assured by him that the delay in publishing has been caused by the exigencies of business and absence from home. The new session commences on Thursday next, the 11th inst., and the Hon. Secretary anticipates new life being thrown into the meetings during the forthcoming session, having received many assurances from members of interesting communications, &c., &c.—Eds.]

The usual monthly meeting of the above Society was held in the Manchester Technical School, on Thursday, April 10th. Tea was provided in the basement of the building, which was considered to be an improvement from the old tea-room. Mr. John Pollitt, the President, occupied the chair.

The proceedings of the previous meeting were read and confirmed. Mr. W. L. Heaton was elected a member of the Society.

Mr. Edwards read a very interesting paper on the importance of rising-fronts, and exhibited several negatives intended to demonstrate the advantage of rising-fronts instead of swing-backs.

The Chairman said he had given considerable attention to the subject of swing-backs and swing-fronts since the last meeting, and had made a few experiments, one of which he desired to submit to the meeting. He (the Chairman) took a double column of *The Times* newspaper and pasted the printed matter on a sheet of stout cardboard. These represented about twenty-four inches in length. On the margins of the printed matter he had marked off every inch from the top to the bottom, and that eighteen inches from the top, and therefore six inches from the bottom, he drew a thick black line across the printed matter so as to be easily distinguishable. He then fixed this against a wall with the camera and lens in front, at such a distance that the twenty-four inches of printed matter exactly filled the focussing-screen. He now elevated the columns to such a height that the eighteen-inch black line from the top was level with the axis of the lens and camera. Thus in this position it was obvious that either the front must be raised or the camera tilted to get the top of the columns on the place. Therefore, in the first place, he raised the front and exposed a plate, and afterwards brought the lens central with the plate and tilted the camera, using the swing-back to bring the plate perpendicular, at the same time keeping the camera or plate the original height from the ground. Another plate was exposed in this manner, and prints from these negatives submitted to the members. The one for which the front only had been raised was sharp and readable in every portion, whilst the one taken with the tilted camera and swing-back was with difficulty readable at the top and bottom of the columns.

Mr. Rishton, Mr. S. D. McKellen, and the Hon. Secretary expressed various opinions on the subject.

Mr. John Warburton exhibited a non-actinic portable lamp intended to be used by tourists when away from home.

The Hon. Secretary said that, for changing plates when away from home, he never used anything more than a piece of yellow paper folded in the form of a tube and secured by two pins, which he placed over an ordinary candle.

Mr. Allen Garnett said he had successfully used the yellow cover of a *Bradshaw's Railway Guide* to protect the actinic rays of an ordinary candle.

The meeting was then adjourned.

The last monthly meeting of the session was held in the Manchester Technical School, on Thursday, May 8th,—Mr. John Pollitt, President, in the chair. The minutes of the previous meeting were read and confirmed.

The Chairman said that being the last meeting of the session he felt bound to draw the attention of the members to a very important subject, and to him not a very pleasant one. The fact was there were a considerable number of subscriptions in arrear—more than one-third of the members having hitherto failed to give the matter that attention which he desired they would now speedily give.

The Hon. Secretary read out a list of outdoor meetings which had been arranged.

Mr. John Schofield exhibited his photographic apparatus, consisting of camera and dark slide, and box for carrying same. The camera was of the ordinary form. The dark slide was similar in construction to a wet slide, but deep enough to hold eighteen plates at a time, which were separated by sheets of opaque paper. The box for carrying the camera and slide also answered for a changing-box, and, being provided with an opaque calico sleeve, he (Mr. Schofield) demonstratod the ease with which he could change the plates in his dark slides. He said he had used the apparatus for some considerable time most successfully.

The Chairman opened the subject of new rooms, and the ideas entertained by the Literary and Philosophical Society, for discussion, in which Mr. Rainor, Mr. Brothers, the Hon. Secretary, and others joined.

Mr. A. Brothers exhibited some photomicrographs taken on half-plates by the aid of the electric light, which had been placed at his service at Owens College.

Outdoor Meetings.—These commenced May 31st, with a visit to Liverpool; June 14th, Gawsworth; June 21st, Miller's Dale; July 3rd, Chester; July 12th, Matlock; July 26th, Speke Hall; August 2nd, Bettws-y-Coed; August 13th, Kirkstall Abbey; August 16th, Middlewood; August 23rd, Bollin Valley.—The last outdoor meeting will take place tomorrow (Saturday), the 6th inst., to Chelford.

The next ordinary meeting will be held at the Manchester Technical School, on Thursday next, the 11th inst. Tea at 6.30. There is every prospect of an interesting meeting.

Correspondence.

"EDWARDS'S MACHINE FOR COATING PLATES."

To the Editors.

Gentlemen,—Your correspondent, Mr. S. Fry, seems somewhat troubled in his mind with regard to the novelty of my patent machine for coating plates, to which he takes exception on the ground that certain parts of the machinery are already in use for other manufacturing purposes, a long string of which he enumerates.

Mr. Fry has evidently quite misunderstood the nature and object of my invention, which is not adapted or intended for the manufacture of "floor cloths," "medical plasters," or other purposes named by Mr. Fry. The machine is simply designed to facilitate the manufacture of perfectly-coated plates in large quantities, and to obviate the well-known defects which have been found so detrimental in plates coated by any of the appliances hitherto used for the purpose.

I feel sure that a little further consideration will enable Mr. Fry to set his mind perfectly at rest as to the validity of my patent, the claims of which have been carefully considered and will be stringently maintained. I shall, however, be willing to grant licences on equitable terms to other plate-makers who may desire to benefit by my invention.

The chief point about the machine (which in its present form is the outcome of a long and costly series of experiments) is the perfect manner in which, with astonishing rapidity, it does the work for which it is designed—in this respect surpassing my most sanguine expectations—while each day furnishes fresh proof that the introduction of a more perfect method of coating than has hitherto been used will prove a boon that will be thoroughly appreciated by the users of dry plates, as well as ensure an

enormous saving in wages and waste to those manufacturers who decide to avail themselves of my improved machinery.—I am, yours, &c.,
The Grove, Hackney, September 2, 1884. B. J. EDWARDS.

To the EDITORS.

GENTLEMEN,—Referring to the letter of Mr. Samuel Fry, in your last issue, relative to Mr. B. J. Edwards's patent: as that communication contains an error in principle permit me space to point it out.

A patent may be obtained for a new application of a previously-existing piece of apparatus. This being the case, it will not only be necessary for Mr. Fry (should he be inclined to contest Mr. Edwards's patent) to show that the apparatus as it now exists *as a whole* has been previously in use, but that it has been in use for coating plates with gelatine emulsion. If he can do this the patent would certainly be of no avail.

It will not, I apprehend, suffice to say before the Vice-Chancellor that because one part of the machine has been utilised in the manufacture of pigments, another in the manufacture of floor-cloths, and a third in the application of gum to stamps, that, *therefore*, the patent is not sound when a machine is constructed, as a whole, even of parts previously well known, for a purpose different from any of those mentioned. However, law—and especially patent law—is a curious and somewhat whimsical thing.—I am, yours, &c., A PATENT AGENT.
September 1, 1884.

To the EDITORS.

GENTLEMEN,—Really inventors, or would-be inventors, should, to save themselves from chagrin, study well previous inventions. I am led to write this after perusing the specification of Mr. B. J. Edwards's plate-coating machine in your issue of August 22nd.

A machine the same in principle has been used in our works for ten years for laying an even coating of plaster of Paris cream upon wood and veneer. The same machine is constantly used by oil-cloth manufacturers, india-rubber coaters, and chemists for rolls of diachylon plasters.

Mr. Edwards does wisely in not claiming the emulsion trough or endless bands; but the scraper—which, he says, is the pith of the invention—is part of the machine used by the manufacturers I have named. His patent is no more valid, I am afraid, than his "patent-grooved plate-boxes," which patent would not stand one hour's cross-examination before the proper tribunal.—I am, yours, &c., JOHN MURPHY.
Liverpool, September 3, 1884.

INSTANTANEOUS SHUTTERS.

To the EDITORS.

GENTLEMEN,—I notice in your issue of today a letter from Dr. Mantell on the above subject, in which he complains that Cadett's so-called instantaneous shutter is not rapid enough to take moving objects. My own experience of this shutter quite corresponds with his. Dr. Mantell goes on to give the features that a drop-shutter should possess. I believe the one I now use fulfils all the conditions he enumerates.

It is a mahogany case $3\frac{1}{2} \times 2\frac{1}{2} \times \frac{3}{4}$ inches. The drop is made of silk working on a roller containing a spiral spring. The exposure can be regulated from very slow to as rapid as a flash of lightning. It causes absolutely no vibration whatever, and is so simple as to be very unlikely to get out of order. The drop is either released by touching a spring or by the pneumatic ball. The size given above is for a lens with a hood an inch and a-half in diameter. The cost, complete with pneumatic ball and tube, is about 17s. 6d. It was made by a Mr. Kershaw.

The above shutter is the only one which I have come across that fulfils the following conditions:—A drop-shutter acting either slowly or with *great* rapidity; capable of adjustment as to the rapidity; working with full aperture; and falling so smoothly as not to cause any vibration to the camera.—I am, yours, &c., R. GALLOWAY-BELLRINGER.
Patricroft, Manchester, August 29, 1884.

Notes and Queries.

"ARE there any means by which rancidity in oils can be prevented or cured?—H. J."——In reply: A few drops of nitric ether added to oil is said to prevent its becoming rancid; and, not only so, but even to destroy the disagreeable smell of oil that has already become rancid.

JASPER writes:—"I have had a valuable photograph entrusted to me for copying, and my clerk has allowed a large drop of ink to fall upon it. How can this be removed?"——We reply: Let "Jasper" try the effect of an application of hydrochloric acid by means of a brush, subsequently washing thoroughly with water.

W. E. inquires:—"Can you inform me in your *Notes and Queries* if there be any work published dealing with the history of photography—I mean giving a description of how it was found out, &c., and, if so, where I can obtain it?"——In reply: Hunt's *Manual of Photography* published by Messrs. Griffin and Co., London, contains a reliable history of photography in its early days; but, as it may be difficult to obtain a copy, we also refer our correspondent to Tissandier's *History of Photography*, published by Sampson Low and Co.

"PERMIT me the use of your *Notes and Queries'* column to reply to Mr. W. H. Harrison's query, in last number, as to whether my experience in dark slides with a cut-off and with a removable shutter is the same as that of Mr. Andrew Pringle. Although I have some dark slides with the ordinary English shutters I confess my preference for those with removable shutters, and, of course, with a cut-off. By adopting the most ordinary care in inserting the shutter after the exposure has been completed there is no chance of any light being admitted. I am here assuming good workmanship.—J. TRAILL TAYLOR."

"REPLYING from an extended experience to 'B. H. A.,' in your last issue, I think that if he be careful he can secure good results in photomicrographic work with a French eighth-of-an-inch objective. My own object-glass is one of a very narrow angle; but, as a consequence of this, it possesses great penetrative power upon such objects as are within its scope. As a rule, I can produce a good photograph of everything I see, and quite as sharply, too, as I see it. The best effect is obtained when, after obtaining visual sharpness, I give the fine adjustment one-sixth of a turn out. Although I speak in terms of praise of my French eighth-of-an-inch objective, I do not for an instant mean to imply that it is as good as one of higher pretensions, such as emanate from our best English microscope makers.—R. G. FLINT."

"I HAVE a lens three inches in diameter and sixteen inches focus which does not work to focus, being, as I have been informed, over-corrected for colour. Will you kindly inform me in what direction I should make an alteration in the curves so as to bring about a coincidence of the chemical and visual foci? I should greatly like if this could be effected without the present focus being altered—at anyrate to any appreciable extent. I may add that the re-grinding and polishing of any of the surfaces of the lens will not cause me either inconvenience or trouble if I only know in what direction to make the alteration or which surface to operate upon.—FELIX."——We reply: It will be safer for "Felix" to leave the external surfaces as they are, and operate upon the inner or contact surfaces. To make the requisite correction these curves must be flattened, so as to render the flint lens less concave than it is at present. To what extent the radius of curvature must be increased to effect this properly it is quite impossible to say. Grind the surfaces, and only partially polish them; then, having cemented them with castor oil, try experimentally what effect has been produced. If the two foci be now found to coincide, complete the polishing of the contact surfaces and cement with balsam.

J. WILLIAM FOSTER says:—"The other evening I saw in a friend's house a number of photographs that possessed a fine tone, and which I was assured had not been toned by gold at all, but by iron, the toning and fixing proceeding simultaneously. My friend cannot afford me any information with regard to the composition of the toning and fixing bath, so I look to the Editors of THE BRITISH JOURNAL OF PHOTOGRAPHY for aid."——To this we reply: The toning bath referred to must evidently be one described by Mr. Hardwich in a paper on *Positive Printing*, read before the London Photographic Society nearly thirty years ago, as we have never heard of any other toning bath containing iron. The following are the particulars:—

Solution of perchloride of iron	$1\frac{1}{2}$ ounce.
Hyposulphite of soda	8 ounces.
Water	15 ,,
Nitrate of silver	80 grains.

The hyposulphite of soda is first dissolved in thirteen ounces of the water, and the nitrate of silver in the remaining two ounces. The perchloride of iron is then poured into the hyposulphite solution by little and little, stirring well all the time. The addition of the iron salt strikes a fine purple colour, but this soon disappears. When the liquid has become again colourless—which takes place in a few minutes—add the nitrate of silver, stirring briskly. Perfect solution will take place without any formation of black sulphuret. Although this colouring and fixing bath will work well twelve hours after mixing, it is still better at the end of a few days.

WE extract the following from a letter received from Mr. BAYNHAM JONES:—"Clause 6 of the article on "the camera of the future" in the Journal of the 22nd ult. is quite unintelligible to my capacity, and as there may be many others equally stupid you would confer a great favour on them as well as myself if you would, in your next number, render the description more lucid, accompanying your remarks, if necessary, with a woodcut. In the Journal of the 22nd ult. you describe a revolving disc in a camera front at M. de Blochous's establishment at Brussels, and of which it appears that gentleman claims to be the inventor. In the year 1857 I constructed a camera with revolving disc and slide for throwing the lens out of the centre—identical *in every respect* with the woodcut given in the Journal—and which is now in my dark room. I took the idea of the revolving disc from a microscope carrying a series of object-glasses, and in lieu of the latter substituted a slide for carrying the lens. I do not imagine I ever described the invention, as THE BRITISH JOURNAL OF PHOTOGRAPHY was probably not in existence at the above date."——In reply: We presume the article first referred to is that by Mr. Andrew Pringle on *Tourist Cameras and Lenses* (page 533), and to this gentleman we refer Mr. Jones's plaint, merely premising, if it be the sixth paragraph of the article (that about the fastening of dark slides and their shutters) to which allusion is made, that while *we* quite understand every phrase, the subject yet possesses a degree of interest quite sufficient to cause us to desire to hear more about it. With regard to the revolving disc in the camera front, constructed by Mr. Jones in 1857, it is to be regretted that he did not publish it at the time, and thus entitle himself to such advantages or honours as are conferred by publication. But even had he then done so, we question if his claims would not have been subject to objection on the score of novelty: for a camera with a circular, revolving front was described, with a drawing, in our first volume (then in octavo form) in the issue for July 8, *1854*, at page 91, which settles the question of priority.

Exchange Column.

What offers in exchange for Marion's swing, good as new, cost £1 7s. 6d.?—Address, W. G. Helsby, Art Studio, Denbigh, N. Wales.

I will exchange a well-bred fox-terrier bitch, value £4, for a whole-plate instantograph apparatus.—Address, A. F. S. Kent, Corringham, Romford, Essex.

I will exchange a 10 × 8 Ross's rapid symmetrical, new, for a half-plate same make; also Lancaster's or other solar enlarging lantern.—Address, J. Jones, 34, Plantagenet-street, Cardiff.

I will exchange a good quarter-plate portrait lens for four dozen Britannia or other good makers' dry plates, quarter-plate.—Address, R. Taylor, 48, Leigh-street (off Pall Mall), Chorley, Lancashire.

I will exchange a very fine dark tent, on wheels, highly painted, also backgrounds, balustrade, pedestal, &c., for a second-hand tricycle.—Address, James Bremner, 1, St. James-road, Forfar.

I will exchange a 19 × 16 camera, swing-back and folding tailboard, extending about thirty-eight inches, in good condition. What offers?—Address, W. Hudson, 62, High-street, Bordesley, Birmingham.

I will give good exchange in watches or jewellery for a good bellows-body camera, half-plate, and good half-plate portrait lens by any good maker.—Address, B. Pearce, Doll-street, Machynleth, North Wales.

Wanted, a good posing-chair, with changeable backs if possible, also a background, interior or exterior, in exchange for a brand new single-breasted frock coat, best quality broadcloth, never worn, chest measure thirty-nine inches.—Address, Horton and Co., 26, Caroline-street, Cardiff.

We will exchange a splendid set of beaver furs, consisting of double collar, two lapells, and one large pair of cuffs, just received from America; also a Colt's revolver, forty-five calb., and hunting belt with squares for thirty-two cartridges; also scabbard for knife and pouch, all solid leather, and silver-mounted dagger and case, for a portable or rapid symmetrical lens and 10 × 12 camera with dark slides, must be in good condition and by a good maker; photograph of any of the above two stamps.—Address, Brook and Steggles, High-street Studio, Shepton Mallet, Somerset.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

Notice.—*Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a* nom de plume *as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.*

Photographs Registered.—

Edwin Smithells, Rivington, near Chorley, Lancashire.—*Photograph of The Unfamiliar Tune; Shadows; Who's There?; Her Fortune; A Reverie; Just Let Loose from School.*

W. S. S.—See a leading article in the present number. We shall have more to say on the subject shortly.

Jas. Wilson.—Doubtless it is a mere idle rumour, with no foundation whatever in fact. Pay no attention to such nonsense.

O. O. O.—The process is worked as a secret one; but it is generally understood to be a modification of Mr. Woodbury's. So you are quite right in your surmise.

Syntax.—Do not go to the extra expense of a rack-and-pinion adjustment for the landscape lens. The rackwork of the camera is quite sufficient for accurate adjustment.

A. J. R.—At present the material is not an article of commerce in this country. It is possible, however, if a use can be found for it, that it may become so eventually.

James Lugg.—The British Journal Photographic Almanac is published at this office. The Publisher will forward you a copy on receipt of one shilling and threepence in stamps.

Hants.—The small quantity of lime in the water, as shown by the analyst's report, will do no harm to the prints. There is no necessity to give them a final washing in distilled water.

R. Michell.—Yes; you will require the permission of the authorities to take views in the streets of Paris; but such permission will be readily accorded if you apply in the proper quarter, stating the purpose for which you require the views

Wm. Biggs.—The reason the transfer paper does not adhere to the collodion film is that you have not sufficiently softened the gelatinous coating. If it do not soften in water at the temperature you have employed it is clear that you have added too much chrome alum in its preparation.

E. J. Lovejoy.—Surely sufficient has been said on the subject in our columns during the past year or two. Refer to your back numbers and you will find all you require to know. You had better remove the boiler from the dark room altogether, as it is very much out of place in such an apartment.

T. A. G.—Very much will depend upon how you place the sitter, and how you intend to use the light. You should not have much less than ten feet of glass at the top and side of the studio. It is better to have a trifle too much than too little, as, in the former case, you can stop some off if not required.

J. J. B.—There is nothing better than plumbago for rendering the gelatine moulds conductive of electricity. You must use the best quality of plumbago, such as is prepared specially for electrotyping purposes.

B. R. J.—The subjects are well chosen, but, unfortunately, all the pictures are marred by the shadows being so deep. This arises from under-exposure. Had you given double time the pictures would, doubtless, have been perfect.

S. Bailey.—If, as you say, all your albumenised paper, subsequent to sensitising, acquires a metallic lustre after hanging for an hour or two, and there is always a bad smell in the room, the sooner you have the drains of the house examined and set right the better it will be for your health, and also for convenience of working.

Aeolus.—Is it an established fact that a longer exposure is required when the wind happens to blow from the east? If it be so with collodion, it will certainly be the same with gelatine plates and also with printing. The light on the western side of large towns is, it is true, somewhat slower when the wind is easterly, because it blows the smoke and fog, if any, in that direction. But the same applies to any other direction, according to the situation.

Self Taught.—1. The sketch shows the studio to be a very useful one if you increase the quantity of glass in the side and roof. There is no advantage to be expected from the small window in the south side.—2. To photograph the church you will require a wide-angle lens of the rectilinear or symmetrical type.—3. Clearly the faults of the illumination. You do not manage your light properly. Without seeing an example of your work we cannot suggest a remedy.

W. A. K.—1. There is no objection to your drying the prints between folds of blotting-paper—that is, if the paper be sufficiently pure, so as not to contaminate the prints. You must bear in mind that some blotting-paper is made with very impure materials, and is quite unsuited for the purpose.—2. The best plan is first to remove all the scratches from the burnishing bar with a piece of snake stone, then polish with a piece of charcoal, and finally burnish with a burnisher, which may be purchased at any toolmaker's.

J. H. P.—We certainly should not advise you to make the proposed alteration in your studio. As it is at present you should be able to get all you require. If you cannot, then it is your own fault and not that of the studio. Instead of putting in a south light, paper the south side of the room with some light paper, so as to soften the shadows by reflection. If this do not answer sufficiently well, use a reflecting screen on the shadow side of the sitter. If you send us a picture or two, showing what you complain of, we shall be happy to advise you further.

Received.—H. Victor Macdona, M.A.; Andrew Pringle; &c.

Photographic Club.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 10th inst., the subject for discussion will be—*On the Effect of Different Alkalies in the Development of Gelatine Plates.*—The Saturday afternoon outing will be at Hale End, leaving Liverpool-street Station at 2.2 p.m.

Those Feet.—"Look here, Mr. Photographer, what in the world did you want to turn my toes in in that style for?" exclaimed an exasperated customer, exhibiting a picture which the artist had just finished for him. "Well, I thought you wanted the picture to be natural," explained the polite artist. "So I did; but I don't turn my toes in." "No, perhaps not. But you see, the picture would not be natural without your feet, and I was obliged to turn them in to get them in the picture."

LONDON GAZETTE, *Friday, August* 29, 1884.

Scotch Sequestration.

Hugh Thomson (deceased), Perth, photographic artist.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician,

For the Week ending September 3, 1884.

These Observations are Taken at 8.30 a.m.

Aug.	Barometer.	Wind.	Dry Bulb.	Wet Bulb.	Max. Solar Rad.	Max Shade Temp.	Min. Tem.	Remarks.
28	29·66	W	61	60	118	70	54	Raining.

JOURNAL OF PHOTOGRAPHY.

No. 1271. Vol. XXXI.—SEPTEMBER 12, 1884.

ANOTHER METHOD OF AVOIDING GRANULARITY IN COPYING PAPER PHOTOGRAPHS.

It will be remembered that a fortnight since we devoted a leading article to a method of producing copies of paper photographs in such a way that the granularity, always so objectionable in reproductions from photographic prints, may be avoided—well, if not actually avoided, at least reduced to such an extent that it would really require a stretch of imagination to conceive that they were actually produced from a paper picture.

At the time we wrote we had merely an opportunity of seeing the results, and of describing the method by which they were produced. Since then, however, we have put the method into practice ourselves, and find it is capable of accomplishing all that was claimed for it, and some of our friends inform us they have done the same. As a matter of course, when a picture has to be produced by double printing it not only entails double time and trouble in the manipulation, but it necessitates something more in practice, namely, the risk that the registration in the second printing may not be coincident with the first, particularly when the work has to be delegated to more or less careless assistants. When this occurs the prints are, of course, lost, which necessitates a delay in the execution of orders and also increased cost of production. Still the method, if worked with care, is one that will always be valuable.

Seeing the objection to a process of double printing in everyday practice being generally adopted, more particularly when a large number of copies are required, we have tried a few experiments to see if this difficulty could not be obviated, and similar or equally good results be obtained by simpler means, while utilising the same principle but in a different manner.

Most of our older readers will doubtless remember that many years back (and long before retouching the negative became such an important adjunct to portrait photography) the late Mr. A. Claudet introduced a method of ameliorating rugosities—always so painfully apparent in large direct portraits when taken with a well-corrected lens. The method of Mr. Claudet was to alter the focus of the instrument while the portrait was being exposed, and, as the movement of the whole of the combination would entail the risk of shaking the camera, he devised the plan of altering the focus by making the components of the lens advance towards, or recede from, each other by a clockwork or similar contrivance. So far as we are aware this ingenious method of working was confined almost, if not entirely, to the inventor himself. But Mr. Claudet's plan of destroying excessive sharpness in any one plane no doubt led to the introduction of a form of lens in which a certain degree of spherical aberration could be introduced into it at the will of the operator, so as to counteract the excessive sharpness produced by a well-corrected photographic lens.

Every observant photographer is aware that there is a considerable difference in the appearance of a picture taken with a lens possessing a considerable amount of spherical aberration—or, to speak more popularly, one that has no real focus at all—and a picture taken with a well-corrected lens purposely put somewhat out of focus. The former will be the far more satisfactory picture of the two. But perhaps, after all, the plan of Mr. Claudet would give a better result than either, inasmuch as part of the exposure can be given with the lens in perfect focus, which will secure a positive amount of sharpness, while the remainder, with the altering focus, will, as it were, soften it off or diffuse it, so that in the end a picture will be obtained somewhat of the Denier character Now this is just the plan we are about to describe for copying paper photographs so as to avoid the grain, namely, altering the focus of the lens during the exposure of the negative. We shall here describe our experiments, which anyone may repeat and thus satisfy himself as to the utility, or otherwise, of the method.

A *carte de visite* was selected purposely with the paper somewhat coarser than the average, so that the experiment should be the more crucial. This was secured in position so that it was illuminated with a strong side light—the system we have long advocated for copying photographs. A copying camera, furnished with a lens of the "rapid" type, was now arranged so that the image should be enlarged to somewhere about double its dimensions. The image was focussed as sharply as possible, a large aperture being employed; and, a negative having been taken, this negative was, of course, sharply and crisply defined. The system of lighting adopted had ameliorated the grain very considerably from what it would have been had a front light been used; but it still bore unmistakable evidence of being a copy from a paper print.

The back of the camera was now marked so that the actual focal point of the lens should be known. The focussing-screen was then replaced, the image examined, and the back of the camera racked out until it was slightly, though palpably, out of focus, it being marked at this point also. It was then adjusted to the first mark, so that it was once more in focus. A second negative was now taken, but in this manner:—When one-half the exposure was made the lens was capped and the back of the camera racked to the out-of-focus mark, and the exposure completed. This negative was a great improvement upon the previous one, so far as the granularity was concerned; but there was too much blurring or lack of sharpness in the image, and the copy had a more or less doubled appearance.

The next experiment was conducted as follows:—The back of the camera was adjusted to the focus mark, the image examined, and the back racked out until the image was again out of focus (but not nearly to the same extent as in the previous experiment), and a fresh mark made. It was now racked inwards beyond the focal point until the image was correspondingly out of focus in that direction, and another mark made at this point.

A third negative was now taken—half the exposure being made this time with the image exactly in focus, one-fourth with it within the focal point, and one-fourth with it without the focal point. This negative was eminently satisfactory; for in the prints made from it the granularity was practically *nil* and the picture sharp, although it could not be pronounced crisply so. In general appearance the copy closely resembled those we described a fortnight since, which had been produced by double printing. The first exposure appeared to secure sharpness, and the subsequent ones a certain degree of diffusion which destroyed the granularity, similarly as did the first and second printing as detailed in the previous article. The copies certainly had no appearance of being taken from paper photographs, and, after they were trimmed and mounted, few would suspect that they had been.

It need scarcely be mentioned that, in adopting this system of copying, it is essential that the alteration of the focus be made with the back of the camera and not by a movement of the lens; otherwise its conjugate focus will be altered.

DISSOLVING PHOTOGRAPHIC VIEWS.

By the term "dissolving" we do not here mean the chemical act associated with the action of solvents upon the substance forming the view, but that optical phenomenon of one picture, while under examination, being gradually and imperceptibly superseded by or "dissolved" into another. Hence the origin of the term. It has hitherto been effected by the agency of a pair of optical lanterns, their respective images being projected upon a screen, the light from one being gradually subdued in proportion as it is increased in the other, producing the effect of both images at one stage of the progress being equally blended, followed by one of them acquiring strength and the other disappearing.

When a succession of views are shown by a single lantern the act of supplanting one by another produces an exceedingly awkward effect upon the screen, the whole act of the transition being witnessed by the spectators, who watch the withdrawal of the exhibited picture at one side and the approach at the other of that by which it is to be superseded, and which the inevitable "small boy" of the audience usually hopes to see displayed upside down—a hope in which he is too often gratified. This changing of the pictures is the *bête noir* of displays by the single lantern. A better effect is obtained when, as soon as the new picture is ready for insertion, the lens is capped and the screen allowed to remain dark until the change has been effected. But this, also, apart from its clumsiness, is attended with unpleasantness.

In previous issues we have described means by which, through the prompt pulling of a string, one photograph succeeds the other with an incredible degree of rapidity; but still the motion from side to side, quick though it be, takes place under the cognisance of the spectators. How to get rid of this formed a problem for solution. We have now the pleasure of giving full details of a method by which the presenting on the screen of a succession of pictures can be effected without any drawback whatever, every one of these having been eliminated.

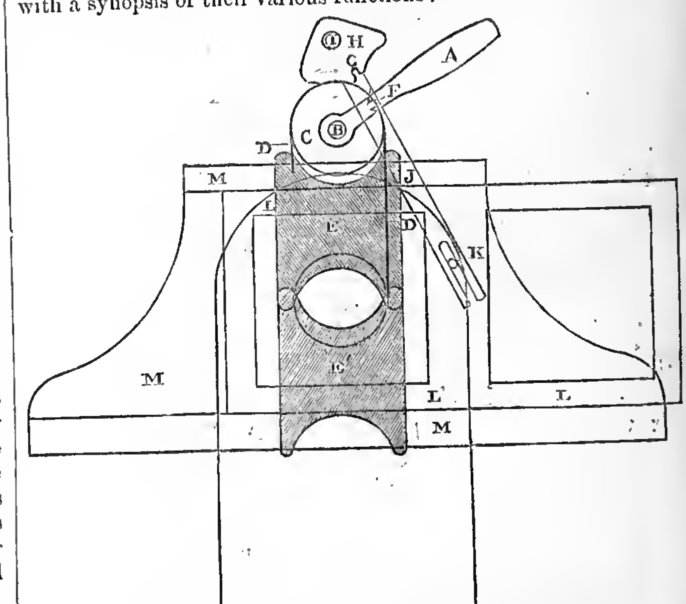
Those acquainted with the phenomena connected with the persistence of vision know that when the eye has been examining any bright object the cessation of the impression of that object upon the lenses is not concurrent with its withdrawal from actual inspection, but that for a brief though measurable period the impression still remains upon the retina. The zigzag path of the lightning and the circle of light formed by the ignited and whirling stick are familiar examples. If a picture or any printed matter be laid on the table, and, while being looked at, the open hand be passed across the line of sight, the senses are scarcely aware of any break or cessation in continuous, uninterrupted vision having been made. In like manner, if the light passing from a lantern to the screen were interrupted for an exceedingly brief period, such as that occupied in making a deliberate blink of the eye, such cessation would scarcely be appreciable. Now, by the new system of dissolving, the lantern is first of all made to blink or, more correctly, to wink its eye by the quick motion of a shutter attached to the lens; and during the moment that the "wink" is being made, and while yet the shutter stands in front of the lens, one picture has been removed from the optical axis of the lantern and another made to take its place. The consequence of this is that when the disc is once more illuminated by the continuous action of the shutter, which has been moving all the time, it is seen that it is now no more the same but quite a different picture which meets our vision. No motion of either of the pictures—the outgoing or incoming—is apparent, for every change was automatically effected before the shutter was allowed to uncap the lens.

As we have described it, the change of one view to another has been supposed to have been effected during a species of "wink," but this may be prolonged to any desired extent by the exhibitor. If preferred, a quarter or a half minute may be occupied in effecting the change. In this case the phenomenon presents the appearance of a gradually-diminishing illumination of the picture on the screen until it passes into total darkness, from which state it gradually increases up to full intensity of illumination, but with a different picture from that which disappeared with the cessation of light. How is this done? We now proceed to answer this question.

We first of all describe the means by which the light is managed and cut off at the proper moment. Erected on the hood of the lens, or by any other convenient means, is a light frame provided with grooves in such a manner as to allow two slipping-slides to pass up and down in front of the lens close to, yet not touching, each other. The ends of these shutters are formed with a hollow or semicircular curve, so that if one be drawn up and the other pulled down there is a stage of progress arrived at by which a circular opening will be formed, and this is obtainable by either end of these sliding shutters. They are operated by strings which pass over a pulley, one at each side, so that by the partial rotation of the axis on which the pulley is fixed one string is wound while the other is being unwound, resulting in one shutter being raised and the other lowered by the same operation. By the sweep of a handle or projecting lever fastened to the axis of the pulley the sliding shutters can be so actuated that when the lever is at either side the lens is open, but when centrally situated between the course it has to travel the lens is closed.

We have next to explain by what means the pictures are changed. A double lantern slide-carrier is made to travel with facility from side to side of the optical axis in a frame by which such movement is facilitated, and which has previously been described in this Journal. In *that*, however, the movement was effected by pulling a string; in this it is effected by a metallic lever, which is forked at the end and actuates a short stud fixed on the division bar of the carrier, the axis of the lever being a rod or axle, one end of which works in a frame just over the condenser or nearly so, the other being carried forward to the objective, where it carries a segment of a wheel containing only one notch. Into this notch works a single tooth, either projecting from the pulley before mentioned or forming part of a separate disc, working on the same axis. When, by moving the lever handle, the pulley is revolved, the single tooth of which we have spoken falls into the notch of the segment on the axis above, by which the lever, acting upon the stud in the carrier, causes this latter to move swiftly to one side.

We here append a diagram showing the various parts mentioned, with a synopsis of their various functions:—



A is the handle or lever which, being fixed on the axis B, causes the drum or pulley C to revolve. On the pulley C, suspended by cords, are two opaque metal plates or diaphragms E E', the ends of which are semicircular, corresponding to the aperture of the lens.

In the diagram the handle A is supposed to be rotating from right to left. As it rotates the plate E falls while the plate E' rises, the two semicircular plates gradually overlapping each other, and so gradually closing the lens. By the time the tooth F (which is attached to a disc or wheel also fixed on the axis B) reaches G the lens will be completely closed, and will remain closed in consequence of the plates E E' overlapping each other, until the segment H, which rotates on the axis I, is moved to an equal distance on the other side of the centre. The lever J is also fixed to the axis I, and, by means of the pin K fastened to the central partition of the double slide-carrier L, pushes the slide-carrier, which runs in grooves in the framework M, to the other side, and thus changes the slide during the interval of darkness.

The diagram is represented attached to a sciopticon. The supports for the axes B I, as also the framework and grooves in which the plates E E' work, all omitted so as not to complicate the diagram.

Mr. B. J. Edwards is the inventor of this ingenious lantern appliance, and by arrangement with Mr. George Smith it is expected to be manufactured at an early date.

MODERN DEVELOPMENT.

The present workers with dry plates do not only include among their number those who have been gradually or, mayhap, suddenly weaned from wet collodion; for amongst them must be numbered a large army of amateurs who, utterly ignorant of wet-plate work, have only taken to the art within the last two or three years. Many of either class are indebted to books or to journals like our own for all their communicated knowledge, and not to hints from friends or conveyed tradition. The fact thus exists that a tendency to an imperfect routine governs the mode of operating adopted by a considerable number, and uncontradicted or unmodified recommendations are still followed to the detriment of real excellence and to some slight hindrance to progress in the various operations involved.

It is our purpose here to touch lightly upon some points connected with development, in order to give the less experienced some idea of the progress made, and to indicate considerations which may be lost sight of even by the earnest student of photographic literature.

We may take for example the oft-quoted maxim that in development a guide to the correctness of the exposure, or to the extent to which development has progressed, may be ascertained by observing the "image showing through" at the back of the negative. This has been said over and over again, and we cannot at the moment of writing recal an instance where the recommendation has been withdrawn. Now, as a matter of fact, it is a most misleading instruction. Time was when it was universally true, as anyone may prove for himself if he happen to possess a few plates of a very old brand. Nowadays, however, thanks to the introduction of iodide and the thicker coating of plates, many kinds are made which scarcely, if at all, allow the image to be seen at the back of the plate, although the fullest exposure has been given and the most thorough development carried out.

Of the vast number of photographers now existing the proportion who make their own dry plates is almost infinitesimal. At one time it was the fashion for everyone to dabble in collodion-making, and the same tendency existed as to gelatine plates; but just as photographers then found that practically they could buy cheaper than they could make collodion, so now it is discovered that time and expense are saved by purchasing ready-made dry plates. But, less like collodion experiences, it may be very plainly stated that, apart from questions of excellence or the reverse, the characteristics of the plates in the market vary to a most considerable degree. For this reason it is that the old rule for development may have to be discarded and others learnt. Not only, however, has this fact to be learnt, but other old beliefs have to be modified.

When a photographer purchases plates from a maker who supplies an article of a character entirely different from what he has been accustomed to use he is too apt to employ his old formula without discretion, and to condemn the fresh plates without giving them a really fair trial; for there is notably a great difference between the class of gelatine which one maker employs and that used by another. One is soft and porous, another is hard and repellent; and, further, one may employ chrome alum, and a rival none. In such a case, while one plate will allow the first trace of an image to start very soon after applying the developer, the other may only begin to appear by the time the first has almost arrived at full density. A knowledge of this fact and the acting upon it may save much trouble.

Again: the older forms recommended a very large proportion of ammonia to the pyro., and a small proportion of bromide to the ammonia. At present we may call attention to the fact that the proportion of ammonia to pyro. recommended by plate-makers and employed by photographers is gradually diminishing. While formerly one, two, or even three minims of ammonia were recommended to every grain of pyro., we now rarely find more than one minim advised, and frequently only half-a-minim. Similarly, the proportion of bromide is increasing. Thus, a well-known maker has from time to time recommended all proportions from a-quarter to three-quarters of a grain to every minim of ammonia; and it was only the other day that a recognised authority stated that he preferred equal quantities of ammonia and of bromide—a proportion that would be absolutely startling to some operators. Yet we do not think it at all unlikely that the plate of the future will have recommended a maximum quantity of half-a-minim of ammonia to every grain of pyro., and a far larger proportion of bromide than is now usual.

Intimately connected with this question is the old "latitude-of-exposure" idea; but when a plate is, as a matter of routine, worked with the very utmost quantity of ammonia it will stand without fogging, it is really absurd to talk about latitude when the result of adding the smallest extra quantity of ammonia—the only way of obtaining "latitude" when an under-exposure has been given—will be to produce fog.

The only way to obtain such latitude is to work with a uniformly smaller quantity of ammonia than the plate is able to stand; then a deviation in either way can be made without any very considerable amount of difficulty.

The true function of a bromide is so far very imperfectly understood. If the usual mode of developing is to employ (say) half-a-grain of bromide to a minim of ammonia, it will be found, that if double that quantity of bromide be added, the image will be far slower in making its appearance, and the conclusion in consequence is usually arrived at that some of the effects of exposure have been destroyed by the bromide. If, however, anyone will take the trouble to carefully compare two printed negatives which have been given identical exposures, and developed with the varying proportions of bromide we name, he will find that there is very little to choose between them. We do not mean to say that the effect of over-exposure cannot be counteracted by the use, in time, of a large proportion of bromide; but we do say that there is a very great tendency to confuse the retarding with restraining action. Anyone who has tried to obtain a good negative from a plate which has shown signs of over-posure by the copious addition of bromide knows how woefully disappointed he usually is. A citrate is infinitely better for this purpose, as the literature of our American brethren very plainly shows them to believe; yet in this country very few photographers have even heard of it, and still fewer make use of it.

We have carried our remarks to the fullest length our space will permit, yet we could have added much more to the same effect. We think, however, that we have said quite sufficient to show that the familiar "cut-and-dried" routine of development is still in a transition stage, and capable of producing results in the future far exceeding the average of the present time, though that is undoubtedly of high excellence.

It is rather a serious charge to make against the management of an important body like the Photographers' Association of America that the officers subordinate public weal to private interest; but it has been made pretty openly in an American journal. Accounting for the non-acceptance of Mr. A. L. Henderson's offer to give a demonstration of emulsion-making before the members assembled, the *Photographic Times*' report states that "there was a whisper in circulation to the effect that a prominent officer of the P. A. of A. was too much interested in a certain dry-plate factory to permit any matters relative to dry-plate making to be discussed." This, if true, is encouraging news for American photographers!

The demonstration was, however, given before the Chicago Photographic Association, and led to an exposition of how thoroughly one of the oldest backers of the wet process has changed his mind. In answer to a question regarding the comparative sensitiveness of wet and dry plates, Mr. Henderson is reported to have replied as follows:—"I am certainly well within the mark in saying sixty times. If challenged I should have no hesitation in guaranteeing to make an emulsion one hundred times faster than your ideal wet plate." It is *not* a quarter of a century since the speaker was willing to back himself with a wet plate to beat any gelatine plates extant. The latter have not since grown more rapid.

But is Mr. Henderson correct in his assumption that "by prolonging emulsification at a high temperature iodide of silver cannot exist in presence of free bromide?" There are certainly some anomalies in recorded opinions on the relative affinities of the halogens for silver, and it would not be a bad subject for a special committee, if such were appointed in the interests of photographers.

Before parting with American topics we may here refer to another cruel thing said by one of her own sons—reflecting certainly not on the country nor even on a class. The chairman of the meeting referred to above stated that "he would remark that the Cincinnati meeting was the first photographic convention he had attended *where not one word was spoken about photography.*" What should *we* think if we had to attend a church where no word was spoken about religion? or be compelled to send our children to a school where no attempt was made at education? It is probable we should like it no better than the American photographers are reported to have enjoyed their lot in connection with the recent convention.

The "Sunbeam" balloon will very likely take part in the centenary celebration on Monday next, but whether the ascent will be a photographic one or not will depend upon the weather and light.

Every photographer who has occasion to use loose gas burners for heating or lighting (and who is there who has not?) is aware of the trouble and the nuisance involved in the use of the tubing required to attach them to the supply pipe. Ordinary vulcanised tubing frequently smells persistently and continuously, while the braided or cloth-covered tube, which is fairly effective, entails so much trouble from the need of brass connections both to tubes and burners that it is placed out of court for ordinary purposes. At last, however, the long-felt want of a tube impervious to gas, elastic and convenient, has been satisfactorily met by Mr. Fletcher, the well-known manufacturer of gas burners and furnaces. The new tube is made of two layers of india-rubber, with pure, soft tinfoil vulcanised between, and it is said by the maker to be perfectly effective, he having had it in practical use for some time, and tested it under strong and continuous pressures of gas for some months. Owing to the difficulty of manufacture it cannot be made in great lengths, six feet being the maximum length that at present Mr. Fletcher has been able to make. This fact, however, need occasion no difficulty; a piece of glass tube to join each length of tubing will enable any quantity to be utilised.

A new filter has been proposed—a porous vessel of unglazed porcelain, through which water is to be forced under pressure. One such vessel ·2 metre long and ·025 diameter gave about twenty litres of water daily which was absolutely free from microbia. The fact of pressure being required is likely to prevent the employment of such a means of filtration by photographers, though there is no doubt that the power to obtain water perfectly free from germs must be of value in some kinds of investigation.

In a communication to the Paris Academy of Sciences MM. Paul and Prosper Henry describe results they have obtained in stellar photography. They employed an objective of ·16 metre diameter and 2·1 metres focal length—quite a small instrument—but they have been so encouraged by the results obtained that they are now engaged in making a much larger instrument, ·34 metre diameter, expressly for astronomical photography. The results so far obtained represent upon a square decimetre a section of the Milky Way of 3° of right ascension and 2° declination, showing fifteen hundred stars from the sixth to the twelfth magnitude.

From a foreign source we learn of an ingenious method of testing a substance for small quantities of silver. It is a combination of the ordinary and the blowpipe methods, the weight of the ultimate globule being estimated, with the aid of a lens, by measurement on a scale, and not by a balance. It is calculated that the requirements of correctness to the one-hundred-thousandth per cent. are easily satisfied by this method.

A new use for iodine has been recommended, and one that amateur manufacturers of cameras, &c., may find useful. It is said that tincture of iodine thinned with methylated spirit forms an excellent brown stain for wood, but requires "fixing" by the subsequent use of French polish. The need for the polish can be obviated by adding shellac to the iodine stain.

We do not often find an early publication of scientific novelties in the columns of some of our foreign contemporaries, but it is seldom that so old an illusion is published as that found in *La Nature* a short time since. The curiously droll and puzzling effect of a set of excessively elongated letters, which was first brought out by the Stereoscopic Company very little less than a score of years ago, was brought forward in that usually most readable journal as an entertaining novelty in the number for the 30th ultimo!

Our readers will, no doubt, remember the ingenious fraud of an alleged discovery of a genuine copy of the "Book of Deuteronomy," which was partially unmasked by the aid of photography. A million of money was the price asked from the British Museum for the treasure; but, it is needless to say, it was not obtained. The same ingenious forger was successful in selling another of his efforts—a "Book of Numbers"—to a Philadelphia *savant.* When the "Deuteronomy" fraud was exposed this gentleman began to get uneasy. He had been furnished with a letter, showing the authenticity of the manuscript, by Professor Tischendorf, and this letter was photographed and a copy sent to Germany. The friends of Professor Tischendorf pronounced it a genuine letter, but Professor Delitzsch furnished ample proof that it referred to a different manuscript altogether! This is another instance of many in which the forger has a very opposite feeling to that of thankfulness for the aid of photography.

Apropos of our recent remarks upon the prospect of iridium coatings for burnishers, it may be worth while to draw attention to the singular properties of the so-called "Hadfield steel," made by imparting a considerable quantity of manganese to decarbonised iron or molten steel, in varying proportions according to the object to be attained. The result is a metal combining, in a remarkable manner, properties hitherto considered quite antagonistic—extreme hardness and great toughness.

MORE ABOUT TOURISTS' CAMERAS.

As the remarks made by Mr. W. H. Harrison and myself on cameras appear to have been acceptable to our readers, and as they have elicited an editorial article in the Journal of August 29th, I venture to offer a few remarks supplementary to my former ones on a subject which really is of great importance to tourists. There are so many workers who have special ideas and devices of their own, and so many camera makers anxious to outstrip their rivals in the production of perfect cameras, that I wonder how it is that Mr. Harrison's remarks did not draw forth a swarm of suggestions for remedies to the imperfections he pointed out.

I confess to having misread Mr. Harrison's calculation as to the time he takes to prepare, use, and repack his camera; but even yet I must say that my operations with my largest camera are very much more speedy than his. As I described the operations with the 10 × 8 camera I shall not repeat them, but I shall describe briefly the *modus operandi* with my smaller one ($7\frac{1}{4} \times 5\frac{1}{4}$). The camera has a folding tailboard, the fold not being secured by a screw but by a catch spring. With my finger I release this spring in the very act of lifting the camera from its case; the base-board falls and is instantly secured to the side fold by a sliding catch. There are no screws, it will be seen. The closing is equally rapid. I cannot allow over one second for each operation, when I try to do it quickly. The camera is thus ready in an instant to fix to the stand.

I have already touched upon the operation of fixing to the stand, but I wish to revert for a moment to my packing-case. This is a brown canvas knapsack, with a leather hand-piece so as to permit of its being carried in the hand as well as on the shoulders. Here I may say that I can carry no weight in my hand, and highly dislike a weight on *one* shoulder; but in a knapsack I could carry a man, if he were a "little London porter," as the old joke has it. When I am going to put in my camera the knapsack lies on the side that goes next my back. It has one leather division, on the left of which goes the camera, face up, covered by a canvas flap, on top of which goes my changing-box slide. On the right goes the changing-box; two side flaps strap over, and then a large flap folds over and straps at the bottom. The dark cloth goes below the large flap and prevents accident to the articles inside. One of the shoulder straps has a buckle and the other a hook-and-eye, so that I can swing the whole on to my shoulders and fasten without wriggling my arms into the straps and unduly "shooting my linen." When I say that my camera has gone round the world in no other garment but this—that it has travelled by ship, rail, coach, on horseback, and on man-back, and has met with no injury—I guess that comment is superfluous. Further—or, rather, not so far—when I want to carry my camera down stairs only, I carry it in the same receptacle; it is so easy to open and so compact.

I fully appreciate the convenience of carrying the camera with tailboard distended as per the editorial article; but how about the ground glass getting broken? Admitted that it is not likely—asserted that it is possible: my ground glass being protected by tailboard and fold it cannot come to grief, and, as I have shown, how swiftly the camera finds itself in the same state as that of the writer of the article! And how about the slides now lying loose in the camera case? Possibly they were in a partition; but, if so, there must bave been a long, narrow partition into which the tailboard would require to be carefully slipped on repacking. The front of the case falling down is a first-rate idea, and I admit would greatly simplify or do away with my last objection. I never tried a thin millboard case lined outside and inside with bookbinders' cloth, so that I cannot speak of its qualities; but I should be afraid of rain and heat affecting such a box. My canvas case laughs at both, and it has been well tested.

The arrangement mentioned in the same article for carrying the lens with its hood facing inwards and the whole lens inside the camera is a good one, but is suited only to lenses of limited length and to a camera that does not shut so close as I like. I doubt if any camera of mine would so carry the lens which I generally use in the camera. This leads me to another desideratum in cameras: they should close into as small a space as possible. My $7\frac{1}{4} \times 5\frac{1}{4}$ camera closes so that from ground glass to lens back combination is under three inches; yet I have full play of both swing-backs. With this camera and a division I have taken views with a lens of three and a-half inches focus—another very weighty statement. I got a second-hand quarter-plate camera lately, and cannot use the same lens in it for want of shortness of focussing arrangement. Makers are very apt to waste wood, increase weight, and spoil cameras by clumsy swing-back adjustments, and the camera of the future will have ample swing-back without waste or weight of timber. My camera of the past (several years) has all this. Until Mr. Gifford came to my aid with his practicality and pencil, and until I had seen my lens arrangement of August 22nd, I intended to have a front made to carry my lens inside the camera, but now I have changed my mind *entirely*. I have had my camera and lens out in the field, and I am at a loss to find a word to express my satisfaction, unless it be that grand word "galoptious." I hope that the studded adapter will not be lost sight of simply because it entails a little trouble and expense. If those who wish to save time in preparations to take views do not adopt the adapter they have only themselves to blame.

A good camera must have two focussing actions—one "rough," which must be performed rapidly; the other "fine," which must be performed accurately. The best cameras of today are so arranged that "rough" focus is attained by drawing out the back part of the camera, the swing-back arrangements and the focussing-glass coming back together. It is important that this drawing back should be smooth, and that all parts should come and remain square to the camera front. So far as I remember, every camera I have seen is open to the two slight objections—that this extension motion is not quite "sweet; that one side of the back of the camera comes occasionally more easily than the other, and that a careless worker may unconsciously be using a side-swing. I think that some little improvement might be made in this matter by manufacturers, and that the two pinch-screws usually found at the top of the extension might be replaced by something better, such as appears to be hinted at by the writer on page 549. The brass band on which my extending motion is worked has ruled lines, by which the back of the camera when extended can be kept parallel to the front. In practice I have never had any trouble in this matter, but I think it right to mention it as a possible improvement. I should prefer all loose screws to be banished, and these screws on my camera *might* certainly get lost, though I have never seen one off yet.

It now remains to discuss one point where Mr. Harrison and I seem to be at variance, and that is the slides, or, more particularly, the shutter of the slides. We agree that the slides should not slide into position in the camera but push, only he is of opinion that the shutter in front of the plate should come right away out of the slide. Well, the first thing after pulling out the shutter is—you have it in your hand—what do you mean to do with it? It is a loose part to begin with, and we ought to have no loose parts. But it is a light thing; the wind will blow it away, or it will get broken perhaps, so you cannot lay it down. You want one hand for your watch or for your cloth if the wind be blowing, and the other for your lens cap or shutter. If you put it into your pocket, fumbling—if the pocket be not large and the shutter is—no place remains but your mouth! That is hardly good enough, for where can you put your pipe then? Joking apart, let us have no loose, light articles in our hands or lying about either on the ground or on the camera. I still stick to what I said about the fog-danger of these separate shutters. If the "cut-off" be a slip of wood or metal it stands to reason that if the shutter be put back or taken out the least bit off the square, light must get in. If the "cut-off" be rubber or any similar material the same thing *may* occur, and soft, flexible materials wear with friction.

In reply to Mr. Harrison on this point, I may say that my practical experience with this kind of shutter is confined to one slide of a thoroughly-good American maker; but I have examined shutters of this kind by several English makers, and distrusted them all. But, even if safe, I would reject them as highly inconvenient for reasons given above.

It will be seen from my writings on this subject that I think that the "camera of the future" will not be so very different from a first-class camera of today, because the cameras I now possess have done me thoroughly-good service under all conditions in the past; but if anyone will suggest improvements on what I have described in this and my last article I shall be only too eager to embody them all in a camera of the Paulo-post-future, and go forth to the wondering nations with a perfect camera, an ideal implement—a *κάλον κἀγαθον!*

Since writing the above remarks I have seen The British Journal of Photography of the 5th instant, and I think Mr. George Smith's remarks, where they touch upon what I have already written, call for some reply from me. In most respects Mr. Smith and I are perfectly at one, and both of us seem to think that Mr. Harrison's camera must be rather out of date.

Where Mr. Smith and I seem to be furthest apart is in the matter of the pulling-right-out shutter. Mr. Smith says I condemn this system, because, as he can only suppose, I never tried it. Whatever may be my demerits as a contributor to this Journal, good faith with its readers is not one; and it would be a want of candour and truth on my part to condemn anything without trying it. As will be seen above, I have tried such a shutter.

Mr. J. T. Taylor, in response to Mr. Harrison, says that he prefers the removable shutter, "the most ordinary care being taken." That is the very point I would be at. Mr. Harrison wanted a camera to rig up in the minimum of time and, as I suppose, with the minimum of care; and for such a purpose the removable shutter is not adapted so well as the ordinary one, because a little care is required to prevent access of light to the plate. I see Mr. Smith puts his focussing-glass in his pocket; if he do that, of course, he may put his shutter there also. My coat would require to be *all pocket* to hold my focussing-glass and shutter sometimes.

I have not now by me my former article on cameras, so that I do not know exactly how I expressed myself as to the fixing of the camera to the stand; but I certainly did not mean that the camera was to be instantly fixed immovably to the tripod head. All I meant was that there should be no fumbling in trying to get the point of a screw into the hole in the camera. There might be guides for the camera to be slipped into, and the pinch may be effected with half a turn of a screw when the camera was properly directed.

Mr. Smith's experience or opinions differ widely from mine in the matter of cameras for instantaneous work. He thinks they ought to be "without any adjustments whatever." If there be a time when side-swings and back-swings are required it is when instantaneous work is on hand; the lens requires to be but slightly stopped, and by a swing-back the focus of different parts of the picture can alone be effected. Mr. Smith abominates changing-boxes. I do not worship them, but I should be very sorry to be without one for each of my cameras when I go touring.

Beginning at 6.30 this morning I have exposed twenty-two plates—four of them duplicates, and all carefully selected and focussed. I have been at it all day, and I do not expect to lose a plate. I have used ten plates $7\frac{1}{4} \times 5\frac{1}{4}$ and twelve quarter-plates. When one is on a tour and views lie close together it is easy to get through two dozen plates, especially when working for a certain set of subjects, and not merely making pictures. I very much prefer picture-making, but at times one must "shove along." Today I should either have "stuck" or required to change plates away from a house. I think it is a pity not to have at least a dozen plates ready for use without going into a dark room or using a dark box. Mr. F. York told me lately he "did" forty-two plates one day this summer, and I have heard of forty being done before breakfast. I do not recommend nor often practise such feats, but it is well to have the power to do them when wanted.

As to the level on the camera: I admit that generally I can level the camera without it, though I have been deceived. I like my camera very nearly dead level for landscapes as well as buildings.

I have never examined Mr. Smith's camera, which, from my knowledge of Mr. Smith's ingenuity, I can easily believe to be a very perfect article. I have no doubt that his camera contains some of the features of "the camera of the future;" but if I buy a camera from Mr. Smith with the removable shutter I shall also have to buy a coat with special pockets from Mr. Poole.

Not having here (at Ayr) my former articles, I cannot tell to what clause Mr. Baynham Jones refers. On finding this out I shall be glad to endeavour to make myself intelligible.

Andrew Pringle

PROPORTIONS OF AMMONIA, PYRO., AND BROMIDE PER FLUID OUNCE OF VARIOUS DEVELOPERS.

The annexed table is one I have worked out for my own use in order to reduce different makers' developing formulæ to common terms, and thus avoid the necessity of preparing different sets of solutions for each make of plate:—

Name of Maker.	Ammonia	Pyro.	Bromide.		Glycerine, Sugar, &c.	Sulph. of Soda	Remarks.
			Amm.	Pot.			
	Minims.	Grains.	Grains.	Grains.	Minims.	Grains.	
Wratten's—							
"Drop Shutter"	3·00	3·00	·75	..	..	..	
"Ins'taneous"	1·66 to 2·50	3·00	..	·21 to ·31	..	..	
Ordinary	1·66 to 2·50	1·50	..	·21 to ·31	..	..	
Swan's	2·96	1·00	2·22	..	..	..	
Edwards's	1·87	2·10	·23	..	4·20 gly.	..	
Nelson's	12·00 to 12·30	1·00 to 1·84	3·00	..	3·40 grs. sugar.	..	
Thomas's	6·00	1·00	2·50	..	..	..	
Rouch's	3·00	1·26	1·26	..	..	5·04	
Mawdsley's	2·96	1·50	..	1·00	..	..	
Autotype	0·86	2·30	0·30	..	..	..	
Bennett's	5·00	1·50	..	0·60	..	..	
York's	3·00	2·00	..	0·25	¼-gr. citric acid.	..	
Pumphrey's Films	1·88	3·75	..	1·00	1·00 gr. ditto.	15·00	
Captain Abney	2·66	0·90	..	1·35	..	..	*Photography with Emulsions*, page 192.
,, Coll. Emul.	3·00	2·40	..	8·00	..	..	Ditto, page 91.
Canon Beechey's Coll. Emul.	21·82	8·73	..	2·18	..	..	Carbonate of ammonia.

To facilitate matters I use concentrated solutions and dropping-measures. The ammonia I make up to a 50-per-cent. solution with glycerine and water; the bromide to a 25-per-cent., also with glycerine and water; and the pyro. to a 25-per-cent. with alcohol. The proportion of glycerine used is that recommended in Edwards's developer, which I find suits any kind of plate and enables me to use less bromide than would otherwise be necessary.

For convenience sake I write down on a card the quantity per ounce of water of each solution required—in accordance with the above table—for any particular plate, and when proceeding to develope I hang this card in front of me where it can be seen easily. It saves hurried calculations at the last moment; for even when using the simplest concentrated solutions some little thought is necessary to arrive at the right number of minims to be employed, and thus prevent mistakes.

To simplify as much as possible everything connected with the mechanical operations of photography, leaving the mind the better able to devote its energies to the higher branches of the art, should, in my opinion, be the aim of every photographer. The adoption of standard developing solutions, concentrated so as to admit of the use in all cases of minim dropping-measures, would be an important step in the right direction; and, if these were decided upon by a photographic committee, I do not think that any difficulty would be found in persuading manufacturers of gelatine dry plates to employ them in their formulæ and directions for development.

The present want of system is most perplexing and troublesome to any but rule-of-thumb photographers. W. Fredk. Mayes,
Assoc. M. Inst.C.E.

PREPARING WOOD ENGRAVINGS FOR REPRODUCTION BY PHOTOGRAPHY.

Given a magnificent impression from an attractive wood engraving—one in which the effects are produced by bold lines rather wide apart—how can this be photographed so as to present the verisimilitude and character in detail of the original without reproducing these lines? This problem is one which possesses special interest for those who desire to reproduce a series of views of objects of current interest, or of portraits, for the lantern from any of our weekly illustrated newspapers, the magnified lines in which would seriously mar the effect.

If the engraving be one representing the higher order of mechanical excellence — such as those now well known to be characteristic of two of the New York monthly magazines, *The Century* and *Harper's*—a nearly wholly obliteration of the lines may then be produced by the simple expedient of covering the engraving with a sheet of ground glass, the rough surface being placed in contact with the print. Two factors here govern the character of the resulting photograph—first, the degree of coarseness of the ground surface; and, secondly, the local moistening of certain portions by oil or water to which a little glycerine has been added. This provides the means of giving great vigour to certain portions of the picture, leaving the remainder like a soft chalk drawing or pencil sketch.

We have recently had occasion to produce photographs for the lantern from rather coarse-lined wood engravings; and, as the result has been successful, we imagine that the *modus operandi*, if described, will be gladly welcomed by some who may have occasion to convert lines into tints.

Let us suppose that the subject to be operated upon is a landscape. The first thing to do is to get rid of the sky altogether; for, however effective a series of beautifully-printed and graduated lines are in an engraving, they do not look well when thrown upon a screen in a disc of fifteen or twenty feet. With a brush charged with *Chinese white* go over the sky, obliterating all the lines. When this has become dry it will be seen that the opacity of the pigment which has been applied is not so great but that the outline of the clouds, should such have been present, can still be perceived, although only faintly; and by the skilful use of an ordinary blacklead pencil they can be restored with any desired amount of delicacy. This applies also to every portion of the composition in which pronounced lines or cross-hatchings prevail.

The foliage of trees, as a rule, does not require any retouching of this kind; but in many of the trunks of trees the effect of rotundity and, indeed, their whole character are often conveyed by a few strongly-marked lines, which would mar the effect of a picture if reproduced on a large scale. Hence the necessity for stopping them out with the Chinese white and replacing them by the delicate tints of the pencil or crayon.

In portraiture we have seen a coarsely cross-hatched face made quite delicate, and this to such an extent as to render it impossible to detect the nature of its origin. We know of some photographic cabinet portraits of statesmen possessing beautiful gradations of tone the originals of which were rather coarsely-executed wood engravings.

We anticipate an objection that may be made to the working upon engravings with Chinese white and pencil in the manner advocated, namely, their permanent destruction *as* engravings. But while owing to the "white" in question being a water-colour it may be washed off, and the engraving restored to its pristine condition, or nearly so, by being sponged with water, it will be a very easy matter for a photographer to make a *facsimile* of the engraving and effect his stopping-out operations upon *it*, leaving the original quite intact.

PHOTOGRAPHY IN BELGIUM.

[From Our Special Correspondent.]

The Production of Belgian Ordnance Maps by Photographic Aids.

L'Institut Cartographique Militaire, or the Military Map Institution of Belgium, is situated a little outside the City of Brussels, near the *Bois de la Cambre*—an ornamental, richly-wooded park on the outskirts of the Forest of Soignes, which forest stretches for about twelve miles from Brussels to Waterloo. The Map Institution is a section of *L'Ecole Militaire*; it forms the fifth department under the control of the Minister of War of Belgium, and is under the direct supervision of Major d'Etat-major Hennequin. The department was created with several others in the year 1830. The principal work of the department is to produce for the army the best military maps; the public also have the benefit of the results. Before 1860 the Military Map Institution, then known as the *Depôt de la Guerre*, was occupied in preparing the necessary documents and plans for producing an accurate map of Belgium on a large scale. The officers attached to the establishment at that time made astronomical and other observations to secure the commencement of the work upon a sound basis. Between 1870 and 1872 the principal work of the department was the completion of the large-scale maps ($\frac{1}{20000}$). This necessitated the presence of more officials; consequently at this period the department was in its highest state of activity.

From 1872 to about 1880 most of the staff was employed in reproducing the large-scale maps by photolithography; these consisted of 400 sheets to make up the whole map of Belgium. In the course of the same period the engraving of the map of Belgium reduced to the scale of $\frac{1}{40000}$ had been taken in hand and completed, and since the year 1880 the department has been occupied in the revision of its chief work. A brigade of officials is constantly at work surveying; it takes note of any changes, sends the information to the department, and the alterations are made in new editions of the maps.

In the early days of the establishment the Belgian artists became remarkably expert in engraving upon stone—"so much so," says Major Hannot in his official report, that "their specimen maps could so well sustain comparison with the best copperplate engravings, that when one of the specimens was deposited at Somerset House, in London, the English Commissioners, thinking it to be an attempt to mystify them, declared, after consulting all the lithographers of London, that the specimen map could not possibly have been produced by any work upon stone."

When it was resolved to reduce the scale of the Belgian maps from $\frac{1}{20000}$ to $\frac{1}{40000}$ as being more convenient, photography attracted attention as likely to be a useful agent in the work. In 1856 Major James wrote from the Southampton Ordnance Survey Office to the Brussels Academy of Sciences:—"I have sent four of my men to Paris with maps which are to be placed on view at the Universal Exhibition. I have utilised their stay in this town by initiating them into the art of photography. I have furnished them with the best apparatus I was able to obtain, and to-day I am in possession of plans of $\frac{1}{10560}$ reduced to the scale of $\frac{1}{63360}$ with perfect exactitude. I attach great importance to this, because I have obtained the means of making perfect copies, on a reduced scale, of maps such as are reproduced by hand labour, with the advantage that I have a confidence in these reductions which I have not in those done by hand." I have translated this letter from the French, so the wording may not be exactly the same as in the English original.

About the same time General Nerenburger wrote to the Brussels Academy of Sciences that in Paris Messrs. Bisson Brothers were trying experiments for him of the same nature. He had just received a proof 25 × 20 centimetres in size, reduced by photography from a part of a large map. It was very sharp, and all the details visible in the map of $\frac{1}{20000}$ were visible also in the reduction. The paper, however, instead of being white, had a bad colour, and the effects of the spherical aberration of the lens were visible at the margins of the proof. "I am not the less convinced," said General Nerenburger, "of the possibility of applying photography advantageously to the reproduction of maps. For this reason I have asked and obtained of the Minister of War authority to construct an *atelier* to enable me to study the matter seriously, and to make experiments, which professional photographers will not undertake. Captain Libois, who has worked assiduously for one year at this subject, will then be able to continue the experiments he has begun, and I do not doubt that he will finally attain the object we both have in view." Not long afterwards photography was employed to reduce the entire map of Belgium from the scale of $\frac{1}{20000}$ to that of $\frac{1}{40000}$.

The use of photography did not stop here. Photozincography was employed to print off maps of the $\frac{1}{20000}$ scale. This necessitated the intermediate production by photography of negatives to the scale of $\frac{1}{10000}$, and the department is in possession of a map of the entire country on this large scale. The maps to the $\frac{1}{40000}$ scale are printed from engraved plates. Some of the maps of the Belgian Government are turned out in colours by chromolithography.

The head of the photographic department at the Military School at Brussels is Lieut. L. Massaux, of the twelfth regiment of the line. He is an accomplished photographer with great artistic taste, to judge by his paintings in oil colours. He informs me that of the three methods of producing maps on the premises—that is to say, by impressions from copper, zinc, and stone—the best results are obtained by printing from copper. The majority of the maps are, however, for reasons of a practical nature, printed from stone.

In the copperplate process the work begins by the use of the original map as turned out from the hands of the draughtsmen. This map is, of course, drawn with great care from the original surveys, and is usually five or six months before it is finished. It is then enlarged by means of the collodion process to the scale of $\frac{1}{10000}$. Each map is divided into four parts in the enlarging process, and the four negatives measure 40 × 50 centimetres each. This is done in a photographic studio by means of one of Dallmeyer's rectilinear lenses, which has an equivalent focus of thirty centimetres, and gives no distortion in the performance of the work. The camera is mounted upon a heavy four-legged table, which runs upon wheels.

The method of taking the negatives does not differ from that in ordinary use, but the images have necessarily to be strongly intensified to give dead whites and blacks. A trace of chlorine is added to the collodion, and the negative is fixed before any of the fine lines are veiled. The best method of intensifying among all those tried at the Military School is the following:—A ten-per-cent. solution of bromide of potassium in water is made, and this is poured into an equal quantity of a saturated solution of sulphate of copper, bromide of copper being then produced by double decomposition. The presence of sulphate of potassium in the resulting liquid is harmless. The negative is treated with this solution until it becomes white all over. It is then washed, and plunged into an eight- or ten-per-cent. solution of nitrate of silver, which produces such a very black image that it is easier to obtain one fit for the engravers than to obtain one of a feeble nature by this method. The same plan of intensification is used not uncommonly in Brussels by professional photographers when they require deep blacks and strong contrasts in negatives. The operation may be repeated several times with the same negative if desired.

Four positives are copied on paper from these negatives by the ferro-prussiate process. To sensitise the paper two solutions are made as follows:—

Solution A.

Ammonia-citrate of iron............	10 to 12 grammes.
Water.............................	100 cubic centimetres.

Solution B.

Ferridcyanide of potassium	10 to 12 grammes.
Water.............................	100 cubic centimetres.

These two solutions, slightly warmed, are mixed in the developing room, and the resulting bath is protected from the action of light. The mixture is filtered into a developing dish, and the paper sensitised by being floated upon its surface. After flotation for one minute it is raised from the bath and hung up to dry in the dark. The usual time of its exposure to daylight under a negative is about five minutes. It is fixed simply by washing in water. Major Hannot says that this fixing produces two opposite effects, namely, that in the same proportion as the water removes the colour from the whites does it deposit it upon the other portions of the design.

Major A. Hannot has sometimes used another process for making the proofs upon plain paper. He says that for maps it is one of the best, and is not generally known. The paper is first salted in the following bath:—

Chloride of ammonium	2 grammes.
Citrate of soda	2 ,,
Water	100 cubic centimetres.

When the paper is dry it is sensitised upon a five-per-cent. solution of nitrate of silver, to which a few drops of citric acid have been added. The paper is exposed to light under a negative for but a few seconds, for to get good results by development no visible image should be brought out by light. The development is effected by plunging the proofs in the following solution:—

Gallic acid	1 gramme.
Acetate of lead	½ ,,
Rain water, acidulated with three or four drops of glacial acetic acid	4 litres.

When the image is sufficiently developed it is fixed at once in a thirty-per-cent. solution of thiosulphate of soda. The print loses no intensity in fixing. When these operations are properly performed the prints, he says, are of good tone and need no intensification, all the more so because they are required only for the purpose of making tracings.

The white back of the paper proof is then brushed over with blacklead. The leaded side, freed from any loose black dust, is then laid upon a sheet of white paper, and a draughtsman following the lines with a hard point makes a tracing upon the paper below, the under part of the positive being blackleaded. This large tracing having been perfected has to be reduced by photography to the exact size of the design intended for the copper plates. This is done by the wet collodion process, and the exposure is made through the glass instead of with the sensitive film on the side of the glass nearest the lens; otherwise the finished printed map would be reversed.

The reduction is effected by means of apparatus placed on elevated ground, and beneath two wooden huts opposite to each other, the camera being placed in one hut and the map to be reduced under the front of the other, so that the light falls strongly upon it. As the map has to be reduced to the true scale all the apparatus is firmly fixed upon stands of iron, resting on stone foundations, and varieties of substantial rackwork are provided to bring the portions of the apparatus and map into any desired relative positions. The lens used is one by Dallmeyer, of the rectilinear type, thirteen centimetres in diameter and ninety centimetres in focus. Although I am far from being a blind admirer of expensive lenses I am bound to say that Lieutenant Massaux told me that this lens had been tested on the premises against one of French make, and the inferiority of the latter was visible even by simply looking at the image it threw upon the ground glass. The English lens gives an image sharp up to the angles of the plates, and in all respects furnishes a negative true to scale. For some of the work at the Brussels Military School a doublet by Ross is used; it is of thirty centimetres focus, and three inches in diameter. After exposure the plates are carried in their slides down to the main building of the series for development.

As this communication is already long enough I shall postpone the continuation of the description until my next.

THE SUN'S SURFACE.

On the evening of Monday preceding the opening of the meeting of the British Association, the Rev. S. J. Perry, S.J., F.R.S., F.R.A.S., F.R.M.S., director of the Observatory at Stonyhurst, delivered a lecture in the hall of the Church of the Gesu, Bleury-street, Montreal, on *Our Present Knowledge of the Sun's Surface.* The chair was occupied by his lordship Mgr. Fabre, and the lecturer was appropriately introduced by the Rev. Father Turgeon, rector of St. Mary's College.

The Rev. Father Perry, who was received with cordial applause by the large audience present, began by giving some general information of the sun, the spots on the sun, and the magnitude of those spots from the distance, including the rotation of the sun, the gradual changes that take place connected with the development of faculæ, the supposed lagging of faculæ behind sun spots, the coloured vales on sun spots, the moving bodies observed upon the solar surface, the connection between ordinary spots and the fainter markings on the solar surface, &c. Speaking of the determinations of the distance of the sun, he said there were three methods of determining the distance—first, the geometrical method, of which the transit of Venus has been the most permanent of late years, and coupled with the observation of Mars in opposition; secondly, the gravitational method, which will probably later on give the very best results; and, thirdly, the physical method by measuring the velocity of light; but they nearly all give the same result, and place the distance of the sun at about 92,500,000 miles—others giving more weight to the observations of Mars would make it rather greater. He (Father Perry) then gave a brief sketch of his method for obtaining photographs of the sun, and went on to speak of the question of the spot area, in which he treated of the times of the maximums and the maximum which we are just passing through, which was illustrated by a number of drawings of the sun taken during the last four years, and gave his reasons why we should suppose that the maximum had taken place in 1882 or 1883, and also what constitutes a maximum. Some of the spots increased in magnitude up to November of 1882, and have gradually decreased ever since. The spot area, however, was greater in 1883. In 1882 there were two decided maximums—the maximum of April and the maximum of November; but in the following year (1883) there was a great acquisition of large spots, which consequently made the area more extensive than in the previous year. It certainly showed that enormous forces were at work to produce such a spot on the sun. The rev. gentleman also detailed his method of measuring the spot area, and the various phenomena to be found in the solar surface, including the movement of spots, proper motion of spots, repulsion, rapid changes, the connection of spots and faculæ, and gave a probable explanation of the blurred surface of the sun, illustrating his remarks by means of diagrams displayed by means of transparencies. The rev. lecturer concluded by appropriate remarks on the joint cause of true religion and true science, as bringing the world nearer to a proper understanding of the truths and works of the Great Creator.

BOTTLES *VERSUS* GAS BAGS.

My thoughts for some years past having been diverted from things photographic, not till my attention was directed to the subject by a lantern-working friend was I aware of the discussion that has been going on in the pages of The British Journal of Photography on the question of gas explosions, and the relative advantages of gas bags *versus* bottles for the storage of oxygen and hydrogen, and the greater or less chances of explosive mixtures being formed under the respective systems. As soon, however, as I found war declared I buckled on my armour, put my steel pen in rest, and made ready to enter the field with the partisan cry—"A bottle! a bottle! a rescue to the bottle!" A cynical "*bag*-man" insinuated that most men of "the old school" might be depended on as "champions of the bottle;" but, fiercely refuting the imputation, I requested him to remember the question was gas—not spirit—and that the gas-bottle pertained to men of the modern school.

Having been the first person in this country to introduce the gas-bottle system for sale to the lanternists, as far back as 1866, whilst carrying on business at Green-street, Leicester-square, as a philosophical instrument maker—and in connection with the long series of critical articles contributed to Cassell's *Technical Educator* and *Popular Recreator* on *Sources of Light* and *Magic Lantern Construction,* so favourably referred to by Mr. S. Simpson Tomkins, at page 471 in this Journal on July 25th—I may fairly claim to speak with some authority on the subject in dispute, especially as every arrangement described in those articles had been tested by me experimentally, at some considerable cost for construction, my object having been an exhaustive examination of all reasonable suggestions for making the magic lantern a perfect philosophical instrument for educational purposes in place of a toy. The most practical arrangements resulting from that investigation were exhibited at a lecture I gave before the Society of Arts, January 20th, 1869, including the condensed gas-bottle system.

But here, to forestal any protest against my attempting to claim too much, I will give the history of the introduction of the condensed-gas bottle. A Frenchman—one Professor Thorillier—invented an arrangement for the solidification of carbonic acid gas for its exhibition, not only in a snowlike form of falling flakes, but as a solid cake like ice. The late Professor Adams—well known as a science lecturer at the old Birkbeck Institution and at provincial institutions, and as a popular Eastertide lecturer on astronomy at the Adelphi Theatre, illustrated by mechanical lantern diagrams (the originals of those sold by opticians at the present day)—was in the habit of showing the condensation of carbonic acid gas, not only at his own lectures, but at those of other professors of chemistry both in London and the provinces, for the reason that the special apparatus required was not only costly but required considerable experience in its manipulation to render it free from danger. That carbonic acid gas apparatus led Professor Adams to employ it for the condensation of the oxygen and hydrogen he required for his lantern illustrations in his provincial lectures. When advancing age induced Professor Adams to sell off, at Stevens's auction rooms, his splendid collection of apparatus—all exquisitely packed in cases, methodically arranged for travelling—I saw a collection of iron bottles, large and small, for the storage of oxygen and hydrogen in compressed condition, but *minus* the necessary condensing apparatus. On inquiry I found that this essential part was in the possession of Mr. Orchard, who had managed Professor Adams's bottles for some years.

During that sale I arranged with young Mr. Orchard for the supply of condensed oxygen and hydrogen in iron bottles with properly-constructed valves, of the respective capacities of seven and a-half and fifteen cubic feet. Immediately after I issued a prospectus to lecturers and lanternists advocating the employment of the condensed gas system, on the grounds of great portability, non-deterioration of the gases, and *entire freedom from danger in any form,* my authority for such statement being founded on Professor Adams's long personal experience with this form of apparatus during a professional life constantly occupied with lecture demonstrations. All credit for the application of the condensed gas system to the oxyhydrogen apparatus is, therefore, due to the late Professor Adams.

From 1844, when I formed a Students' Practical Chemistry Society (which included several members who have since made a name in the world of science), I have had practical experience with the generation of oxygen and hydrogen and the lime-light apparatus; but from 1856, when I adopted the lantern as the regular method of illustrating my lectures and demonstrations on the microscope and natural history, given in connection with St. George's School of Medicine, I have made the improvement of the oxyhydrogen apparatus a special study; and, having employed water-pressure gas-holders, weighted gasometers, Dr. Woodward's mixed gas apparatus, gas-bags with all forms of pressure-boards, I unhesitatingly say that, after considerable experience with condensed gas-bottles from 1865, I never again would employ any other form of apparatus but as a matter of necessity. My reasons for coming to this conclusion cover the whole field of constructive and manipulative details connected with lime-light apparatus. These may be brought into a kind of debtor and creditor account, well worth the trouble of "totting up" on which side a balance stands in favour. The items we have to consider are—

1. The apparatus required for making oxygen—its cost and dangers.
2. " " " " hydrogen " "
3. " " " storing the gases " "
4. " " " producing the light " "
5. Carriage of apparatus .... " "
6. Erecting, removing, and guarding—its time and danger.

Each of these items shall receive careful and unbiassed consideration in future articles. SAMUEL HIGHLEY, F.C.S., &c.

ON THE TREATMENT OF HUSNIK'S PHOTOLITHOGRAPHIC TRANSFER PAPER.*

THE second bottle, which is intended to contain the solution in use, should only hold about two or two and a-half litres. It is made three-quarters full from the store-bottle, and the other quarter is filled up with plain alcohol. If, through long use, there should be but little of the bath remaining in the bottle, then take three volumes from the store bottle, add one volume of alcohol, and fill up the small bottle again with that.

In using them never pour more than about two-thirds of the fluid contained in the small bottle into the metal bath; in that way one will be saved a good deal of trouble in the shape of filtration, as the dust and other impurities which are taken up in the course of time from the vessel itself, or from the paper floated in it, will, when the solution is poured back into the bottle, settle at the bottom of it, and may be kept back by careful pouring.

After the bath has been poured into the metal dish lay a sheet of photolithographic paper, back downwards, upon the fluid, and with the thumbs press down two corners of one side of the sheet to the bottom of the dish; with the fingers raise alternately the one side and the other of the dish so that the fluid may run over the upper surface of the paper. By frequently moving the dish up and down the whole of the paper is covered by the solution without its being necessary to fix it except at the corners. Now, this is of importance, as any contact with the hand or with any solid object injures the upper surface (which is soluble in water) of the prepared paper, so that at the subsequent development the parts of the picture that had been touched would remain black. When the paper has been in the bath for about half-a-minute take it by the two corners, lift it out quickly, let it drip, and then hang it up by pins to a cord or rod to dry in a dark place.

If one has to sensitise a double sheet, and the metal bath is not so large as the paper, first treat half of the paper as described above; then get some one to hold up the half already sensitised while you sensitise the second half. Should one, however, not have an assistant at hand to hold the paper then proceed as usual to sensitise the first half of the double sheet; but, instead of taking it out at the end of half-a-minute, let it lie a couple of minutes, so that it may not afterwards be able to absorb any more solution. Then raise the paper quickly forward in a sloping direction, so that the part which is still dry may be drawn through the solution and completely wetted. Hold the paper perpendicularly, so that the fluid may run down from the upper perfectly-saturated portions of the paper, and keep the lower longer moist, as it is only in this way that it is possible to moisten the under part equally. In this manner, also, one is saved having to handle large dishes, which also require much more solution.

THE DRYING OF THE SENSITISED PAPER.

So far everything may be done in the light, because light has very little effect upon the wet salts of chromium, and because the bath is quite neutralised by ammonia. But the paper must be dried in the dark, and when dry it must be perfectly protected from light. The drying itself should not take place at a higher temperature than 22° R. Even a temperature of 25° R. may melt the upper and under gelatine films of the paper together, and make the whole useless. In order to learn whether the transfer paper has become spoilt—either by lying too long in a damp place, by the action of hurtful vapours, or by light reaching the sensitised sheet—all that has to be done is to take a tiny strip of the suspected paper, blacken it with the colour usually employed, and in a few minutes lay it in cold water. If at the end of half-an-hour the colour can without difficulty be removed with a sponge then the paper is still fit for use. As in summer sensitive paper will only keep about a couple of days, it is very handy to be able to apply this test to see whether it is still in working condition. It is advisable to keep the well-dried paper in a tin case in a cool place, when it may be kept even for three or four days; and its keeping qualities may be still further increased by putting some carbonate of ammonia into the tin case.

THE EXPOSURE, OR THE PRINTING.

If one have a good negative, in which all the lines and dots are transparent and all the whites opaque, he may feel sure of getting good results. But it must be kept in mind that there should not be too great a difference between the temperature of the drying-room and of the printing place, whether the latter be in the open air or under cover. If it be cold and damp outside, then the paper or other backing of the printing-frame will also be damp; and when the well-dried sensitised paper is placed in the frame it will communicate its dampness to the latter, which will, consequently, become crumpled. It must be borne in mind that the slightest creasing of the paper will cause some lines to run into each other, thus effecting a loss of sharpness. The paper should, therefore, be kept for at least an hour in the place where the printing is done before it is put into the frame. The paper, which has become somewhat damp, is then burnished, in order that its upper surface may become perfectly flat and smooth, after which it is placed under the negative, and a much greater pressure may be put upon it than is done in printing photographs in the usual way.

The burnishing of the paper before printing must be done with the greatest precision, as the flatter the surface is the sharper the image, the finer the lines, and the opener the shadows will be; yet the burnishing should not be continued after the paper begins to become transparent, because then the chromate will be decomposed by the pressure alone just as if light had reached it, and will give rise to spots on the picture. Also, even if it did not prevent the picture from developing properly, a paper over-burnished until it began to become transparent would be useless, because it would not transfer properly, as it would not adhere to the zinc. The length of the exposure depends, of course, principally upon the state of the light, but also partly upon the clearness of the lines in the negative. In the strongest summer sunlight with a good negative an exposure of a minute or even less may do; in weaker sunshine three to six minutes; and in winter sunshine about ten minutes. In the shade in the best light one will require from a-quarter of an hour to an hour, and in winter two hours, or in bad light longer. In printing it is of great importance to have a Vogel's thermometer, furnished with a strip of the same paper as you have under the negative. One usually prints until No. 8 becomes slightly visible. Fogged negatives require longer to print—sometimes twice as long. The printing-frame should not be opened to see how the printing is progressing, as the paper will be more or less expanded by the moisture contained in the atmosphere, and will never be laid down again to a hair on exactly the same line and dot; and this displacement causes want of sharpness, broadens the lines, and makes the dense shadows run together. On this account a photometer is absolutely indispensable;—indeed, one should have at least three to five photometers, as they often require adjustment, and the more work there is to do the more negatives there will have to be exposed to the light that do not print alike.

In preparing the negative plate glass only should be used, as the slightest inequality in the glass gives rise to an inequality in the pressure of the paper upon the negative, and may cause the lines under it to appear either broadened out or contracted. The same effect is produced by the slightest grain of sand or of dust blown between the negative and the paper. On a fully-exposed print all (even the finest dots) must be visible, though in the latter case they need be but slightly so. A print should never be left undeveloped until day on account of the continuating action of the light going on in the dark and widening the lines. Each print must, therefore, be blackened at once with the transfer colour and laid in water, where it may be left for a whole day, if so desired, without the development suffering.

—*Notizen.* *(To be concluded.)* J. HUSNIK.

* Continued from page 90.

WHERE TO GO WITH THE CAMERA.

[It is hoped that this series of articles will be continued at regular and frequent intervals during the vacation months, and we shall be glad to receive contributions to the series from any friends able to treat of new and interesting ground.]

LANGHOLM AND ITS VICINITY.

As this is the time of the year when the amateur photographer is as keen as any August sportsman on the moors to make a good bag, I take the opportunity of giving a few hurried notes of a recent visit I paid to the seat of Mr. Andrew Pringle, at Craigcleugh, Langholm, N.B.

This very beautiful residence is embosomed in a wild cincture of hills, from the summit of which the most enchanting views may be obtained, the purple heather and undulating soil suggesting to the mind of the artist splendid visions of academy honours and distinction. Here I found my host "at home," and ready to accompany me on the following day to "fresh fields of (camera) glory and pastures new."

Punctually at 10.30 a.m. we started, with our slides charged for a few exposures on the banks of the River Esk. The morning was phenomenally clear and brilliant; not a cloud to be seen anywhere, and the light of that tone which always sends a thrill of joy through an artist's soul. It was simply perfect.

We soon found ourselves on the banks of a very fine reach of water, arched in the centre by a most picturesque bridge. Here we exposed our first plate under the most favourable conditions. The rocks in the foreground, water in the middle distance, and well-lighted foliage in the extreme distance gave a very fine effect of light and shade to the view. We exposed a few more plates from the other side of the bridge, which was, if possible, more picturesque than the side we first selected. Had our supply of plates been equal to the demand of the beautiful "bits" of landscape and riverscape on all sides of us we might easily have taken home with us a large "bag;" as it was, we had to content ourselves with only four whole-plate views.

We were amply rewarded for our exertions (as the sun was oppressively hot) when under the fascinating labours of the developing-chamber—*not* dark room. I wish this to be carefully noticed, for Mr. Pringle has no *dark* room. It is a model of lightness and brightness—every article of chemical plant being quite visible—and *soothing* to the eye. Here a pane of green glass, there yellow, elsewhere orange, and last, not least in the enthusiastic laird of Craigcleugh's mind, *ruby*. Anybody once inside that *sanctum sanctorum* would have solved at once and for ever the vexed question as to how most successfully to solve the problem of obtaining "the minimum of actinity with the maximum of luminosity." Our plates, by-the-bye, were not up to our ideal of either exposure or development. *Verbum sat sapienti.*

Next day we early filled our slides and started for another excursion. We had to wipe off our photographic war paint and attend a wedding ceremony—a *Scotch* wedding. Well, I will not venture to describe this function, as it is exactly the reverse of all Anglican prejudices on the subject, the ceremony taking place in the afternoon, and the guests being regaled with tea and cake. Two quick "shots" were taken of the bridal party, which pictures will *not* get the medal.

I forgot to mention that *en route* to the hamlet where the wedding ceremony took place we exposed a few plates on some very beautiful peeps of the river Esk—views which, I am told, received the highest eulogy from the pen of Mr. Ruskin. He is reported to have said that there was no scenery more striking and picturesque in the whole of Scotland.

We returned home late—I mean *early*—after a ball given at the bride's residence, and made early next morning further preparations for a third and last effort to win the Parent Society's medal for landscape work. We went over the same ground until we got nearly as far as the Parish Church of Canobie, and diverged thence to the left until we came to a bridge which spanned an insignificant-looking rivulet near the high road. This was a gem, and no mistake about it. I have never seen anything more truly artistic and beautiful. Long trailings of ivy hung down in graceful festoons along the arches of the bridge; ferns of a delicate species clung to its sides in wanton proportion; and all kinds of wild plants clung to its buttresses in matchless confusion. The lichen was there in all its grey splendour, and the foliage of the overhanging trees gave shelter and balance to the whole picture, the little pebbles in the foreground giving the finishing stroke to as charming and fascinating a bit of scenery as ever delighted the human eye. We exposed two plates with long exposures, and hastened to the end of our drive—Pentone. Here we were to have a picnic and were the *avant-coureur* of our party. It was a Scotch picnic—tea and cakes again.

Before the arrival of the guests to partake of this very innocent refreshment we set up our cameras and exposed a few plates on the surrounding wild rock scenery. This place it is hard to describe. It is the rendezvous for all enthusiastic sight-seers. Travellers flock, I was told, from all parts of England to gaze on these rocks. Many of them are of the most weird and startling proportions—a kind of miniature Giants' Causeway in a rustic glen. No words of mine could possibly describe the beauty of the environment of this place; it must be seen to be realised.

This ended our day's work, and my jottings are now at an end. Moral: Let the reader go and make his headquarters at Langholm, N.B., and if he be not satisfied with the scenery on all sides of him I think he must be indeed hard to please. If it should be his good fortune to find the laird of Craigcleugh at home, and have the honour of the *entrée* under his hospitable roof, the photographic tourist will be a fortunate traveller. It is a liberal education to see all his works of photographic art hanging on his walls, and one day in his company will do more to enlighten the tourist in the mysteries of the "black"—I mean the brilliant—art of photography than all the primers recently published put together. H. VICTOR MACDONA, M.A.

FOREIGN NOTES AND NEWS.

PHOTOGRAPH OF A FLYING BULLET.—SOME DISTINGUISHED AMATEURS.—HOW TO FREE GELATINE FROM GREASE.—PHOTOGRAPH OF A FLASH OF LIGHTNING.—HYPOSULPHITE OF SODA AS AN ANTISEPTIC.—A PERMANENT INDUSTRIAL EXHIBITION.—M. PHILIPPE'S ANILINE PHOTOGRAPHIC PRINTING PROCESS.—ON THE SUMMER TREATMENT OF LICHTDRUCK PRINTS.—GELATINE AND GELATINE DRY-PLATE MANUFACTORIES.—DR. ELSNER'S PHOTOMICROGRAPHIC ATLAS.

ACCORDING to the *Mittheilungen*, Professor Mach, of Prague, has photographed a whizzing bullet which was shot off in a dark room in front of a camera containing a sensitive gelatine plate. The very firing off of the bullet itself caused the discharge of a Leyden jar, which was connected with it, and which furnished the necessary light.

The *Potsdam Zeitung* says that Prince Henry of Prussia is an accomplished landscape photographer, and carries out the necessary processes in a studio attached to the Villa Liegnitz, at Potsdam. Prince William and the heir apparent of Saxe-Meiningen are also said to be amateurs of the modern "black art." The members of the house of Hohenzollern are all obliged to learn some trade or profession, and perhaps some of these three princes have selected photography as the optional branch of industry.

In the *Bulletin de la Société Française de Photographie* M. Scola makes some remarks on the grease contained in many kinds of gelatine, which prevent it from adhering to the glass, and causes specks and flaws in the picture, owing to inequality of development from the inequality of the composition of the gelatine. To remedy this state of matters he recommends the employment of those substances which dissolve grease but not gelatine, such as ether, sulphuretted carbon, and, above all, benzole. The sheet of gelatine to be dealt with is simply laid for a couple of minutes in good benzole, the adherent solution is then shaken off it, and it is rinsed in alcohol. Good benzine may also be substituted for the benzole.

Dr. Kayser, the Vice-President of the Association for the Cultivation of Photography, has sent to the *Mittheilungen* a photograph of a flash of lightning taken on the 16th July. In the print it appeared to be about two m.m. in width, and was distinctly divided into two by a black band, while in the negative the flash appeared to be divided into four parts. The broadest consisted of very narrow, clear, and dark scaly-like marks placed at right angles to the direction of the flash. From the principal ray of the flash smaller rays of lightning branched off on all sides and became lost in the air.

The *Archiv* says hyposulphite of soda is said to be both an extremely powerful antiseptic and a remedy for diphtheria.

The Upper Austrian Industrial Association has opened a permanent industrial museum at Linz, to which photographs and photographic apparatus are admissible.

M. Philippe's aniline printing process consists of floating albumenised or gelatinised paper upon a bath of bichromate of copper and ammonia (ten to fifteen per cent.), drying it, and exposing it under a negative. When a powerful picture has been produced it is laid in a one-per-cent. solution of cyanide of potassium until the whites are quite clear. It is then allowed to drip, after which it is placed in a very acid aniline bath, consisting of—

Water	100 parts.
Oxalic acid	10 ,,
Aniline	1 part.

In a very short time the dye becomes fixed upon the parts which the light had reached, and the picture becomes powerful and assumes a tone very similar to that of silver prints.

The *Archiv* repeats the following hints for the treatment of lichtpaus pictures upon cyanotype paper (dark lines on a white ground) during warm weather:—Keep the prussiate of potassium bath very weak, and keep adding water very frequently to make up for the loss by evaporation. The acid bath should not be too strong, otherwise it dissolves the size in the paper, and it must also be diluted with water from time to time. By exposing the paper much longer the development may be undertaken with a solution of two grammes of gallic acid in one litre of water, instead of with prussiate of potash, but the salt must be completely reduced by the exposure.

The Photographic Society of Frankfort-on-Maine intends to have a general photographic exhibition in the course of this month.

One North American gelatine plate manufactory has offered four prizes, amounting in all to 600 dollars, for the best character portraits taken on its plates; and another manufactory offers four prizes, amounting to 500 dollars, under similar conditions—so that, on the whole, dry-plate manufactories seem to be in a very thriving state in America. The manufacturer of the raw material does not, however, seem to be so fortunate in Germany; for, according to the *Archiv*, a man who set up a gelatine factory at Gera was literally driven out of the place. He then bought an old factory at Weida and resumed business there; but there also police and community joined to interdict the manufacture, and a third start made at Greiz met with no better success.

Dr. F. Elsner has just published the first number of a microscopic atlas intended for the use of health officers, apothecaries, druggists, and persons who are interested in the prevention of the adulteration of food stuffs. The illustrations are reproductions in lichtdruck of microscopic preparations which are photographed direct. The whole thing being done by photogrophic processes, no allowance has to be made for the working of the imagination of the engraver, which so often beautifies but at the same time falsifies and renders untrustworthy the usual reproductions of microscopic slides. As at present projected the undertaking will consist of three series—first, food stuffs; second, textile fabrics; and, third, fresh water animalculæ, to which a fourth, bacteria, may be added if the work meets with sufficient acceptance. The first number contains fifteen figures of microscopic preparations relating to coffee and twelve to tea; No. 2 thirteen figures of cacao and its adulterations; and sixteen of cinnamon and its adulterations. There is an accompanying explanatory text. The microphotographs are from the establishment of Otto Wigand, of Zeitz.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
September 16 ..	Bolton Club	The Studio, Chancery-lane.
,, 17 ..	Photographic Club	Anderton's Hotel, Fleet-street.
,, 18 ..	London and Provincial	Masons' Hall, Basinghall-street.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

At the meeting of this Society, held on the 4th instant, the chair was occupied by Mr. W. K. Burton.

Mr. A. Cowan said that a good deal had been spoken lately of a modification of the alkaline developer introduced by Mr. Monro, of the United States, which variation consisted in the use of the mixed alkalies (potash and soda, instead of ammonia) with pyro. and sulphite of soda, but no restraining bromide. He (Mr. Cowan), in order to make comparative experiments for testing its characteristics, had used six developers as follows:—

No. 1.

Pyro	1 grain.
Liquor ammonia	$2\frac{1}{2}$ minims.
Bromide of potassium	$1\frac{1}{2}$ grain.
Water	1 ounce.

This might be considered as the normal developer with which the others were compared.

No. 2.

Pyro	2 grains.
Carbonate of potash	$12\frac{1}{2}$,,
Carbonate of soda	$12\frac{1}{2}$,,
Sulphite of soda	$12\frac{1}{2}$,,
Water	1 ounce.

No. 3.

Like No. 2, but with the addition of half-a-grain of bromide to the ounce of developer.

No. 4.

Pyro	2 grains.
Carbonate of potash	25 ,,
Sulphite of soda	$12\frac{1}{2}$,,
Water	1 ounce.

No. 5.

Pyro	2 grains.
Carbonate of potash	$12\frac{1}{2}$,,
Carbonate of ammonia	$12\frac{1}{2}$,,
Sulphite of soda	$12\frac{1}{2}$,,
Water	1 ounce.

No. 6.

Like No. 5, but with the addition of one-quarter of a grain of bromide of potassium.

The same subject had been exposed on several plates for a like time, and then treated with the above developers. These plates were handed round, and Mr. Cowan summed up the results as follows:—There was in no case more detail than with the normal pyro. and ammonia developer. In one case—that with the mixed carbonates of potash and ammonia—there was, however, a more vigorous image; but the use of potash and soda with him caused a disagreeable yellow colour. This result was different from that obtained by Mr. Ashman; possibly the make of the plate had something to do with it. Those he employed were made by the boiling process, and contained but very little iodide. A point to remark was that the carbonate of potash and soda developer not only did not require the addition of a restraining bromide, but would not stand it unless the exposure were enormously prolonged. No. 3 solution had refused to act, and when the amount of bromide solution was reduced to one-tenth of a grain the action was very slow, and the picture appeared under-exposed. When No. 6 was employed, which contained only one-quarter of a grain of bromide to the ounce, there was no image after an immersion of ten minutes. He thought that the developer, with the addition of the small quantity of bromide, would be useful for negatives that had been over-exposed.

The Chairman had experimented with carbonate of soda and carbonate of potash, and like Mr. Cowan had found the yellow colour that ensued unavoidable. He had also found that a moderate addition of bromide when using these alkalies instead of ammonia prevented the image from developing.

Mr. A. Haddon said that the yellow colour resulting from the use of soda could be temporarily removed by hydrochloric acid, but that it returned as soon as the acid was well washed out.

Mr. W. E. Debenham inquired whether in the use of the soda or potash developer with bromide, as recommended by Mr. Cowan, the latent image was affected; or whether if a plate upon treatment with it were found to be insufficiently exposed for that mixture it could be washed off and the development continued with a less-restrained or with the ordinary developer. If the latter were the case the development not only of a plate known to be over-exposed, but of one which was thought to be so and was in reality not so, could be successfully carried on.

Mr. Cowan replied that the latent image did not appear to be affected, but that the development could be carried on in the manner mentioned.

Mr. Debenham, referring to the comparison between the normally-developed plate and that which appeared more vigorous, said that the normally-developed one looked to be over-exposed, and if it had had a somewhat shorter exposure than the other the image might have come out with equal vigour.

Mr. J. Barker, adverting to the use of sulphite of soda in the developer (the usual ammonia and pyro. developer he meant), said that he looked upon it as a useless incumbrance and of no advantage, but the contrary. In his hands it gave a grey veil, and the negatives were not so clear as when developed without it.

Mr. Cowan had used sulphite of soda with the potash and soda developer, as it had been included in Mr. Monro's formula; but he had not used it in the No. 1 or normal developer, for in his own practice he preferred to do without it.

The Chairman said that as to the use of sulphite of soda his opinion was much the same as that of the preceding speakers.

Mr. W. Cobb was quite of Mr. Barker's opinion as to the use of sulphite of soda. There was a question he would like to ask—Whether any of the members had had experience of the use of bichloride of mercury as an intensifier when not carried to the usual extent of bleaching and subsequent treatment by ammonia, but in cases where only a little intensity was required by the pouring on of a dilute solution for a time sufficient only to somewhat darken the image and before there was any bleaching action? He had used this method but some months only, and would like to know what were the probabilities of permanence in the results.

Mr. Debenham had at many times employed this method occasionally for thin collodion negatives when they happened to be a little under-exposed. He thought that the results had been permanent.

Mr. W. M. Ashman had also used it in collodion and found that the negatives were permanent; but it did not follow that they would be so with gelatine films.

Mr. Barker said that there had been some controversy lately as to the production of warm colours on bromide plates, one gentleman claiming it as his introduction. He had produced plates with this characteristic as long ago as 1873.

The Chairman had seen a set of collodion emulsion plates produced ten or more years since showing a great variety of colours. This variety was induced by the employment of restrainers.

Mr. Derham, of Boston, U.S.A., showed a double camera for use when taking instantaneous pictures. The camera was fitted with a pair of Voigtländer's Euryscope lenses (which were now most highly esteemed in America for instantaneous views) of about twelve-inches focus. The camera was applied to the shoulder, and whilst the subject was focussed with one lens the other was exposed by pressure upon a pneumatic ball releasing a spring shutter that worked between the lenses. The shutter itself was taken from one described by Mr. Noton in The British Journal of Photography in the year 1879.

Mr. W. Turner was elected a member of the Association.

MANCHESTER PHOTOGRAPHIC SOCIETY.

On Saturday, the 30th ultimo, a considerable number of members and their friends, including ladies, from the above Society assembled at London-road Station, for the purpose of making an excursion for photographic work to the charming and romantic scenery in and around Dovedale. The occasion was not one of the regular trips which have taken place after short intervals during the summer months, and of which a printed programme is placed in the hands of each member at the beginning of the season; but was the outcome of a mutual wish on the part of the Derby and Manchester Photographic Societies, which met a little while ago at Matlock, that a special meeting of the two societies should be arranged to take place at a subsequent date, for the purpose of passing a few hours in friendly rivalry and social intercourse.

The train by which the party travelled left Manchester at 9.20 a.m. and arrived at Ashbourne, "up to time," at 11.50. Waggonettes having been procured, the drive to Dovedale, some four or five miles distant, commenced under somewhat gloomy forebodings as to weather. Happily, however, the threatened rain did not come, and with the exception of a slight shower later in the afternoon the day continued fairly bright. The hotel at which refreshments had been ordered was reached about one o'clock, and a pleasant walk across the fields brought the stepping-stone at the entrance to Dovedale in full view. Here the landscape is charmingly pastoral, but on this occasion it was somewhat desecrated by the presence of sundry sweets' stalls and ginger-beer vendors, as well as an imposing array of "Jerusalem ponies." Accessories such as these, however, were not appreciated.

The members made their way up the valley, and on the arrival at the curious and romantic group of rocks, called the "Twelve Apostles," cameras were quickly opened out and work commenced in earnest. From this point to the termination of the dale at Dove Holes, about one and a-half mile further up the stream, the scenery is of the most varied and delightful description, and the number of views to be obtained may be said to be almost endless. A mass of rocks on the Staffordshire side of the river, called Dovedale Church, Tissington Spires, and Reynard's Cave on the Derbyshire side, each absorbed a considerable number of plates, while quiet pools and picturesque groups of trees presented themselves *ad infinitum*.

The Straits of Dovedale, the Watch Box, Piccary Tor, and a multitude of other choice "bits" in the upper part of the valley, finishing with the Dove Holes, were generally voted too much for one short afternoon, as the latest return train to Manchester left Ashbourne at 6.35 and tea had been ordered for five o'clock. Consequently, when Reynard's Cave was reached the bulk of the party began to wend its way back again, and several other plates were exposed on the return route, the distance from the entrance gate to the "Peveril of the Peak" being covered by the members in straggling file, Mr. Atherton bringing up the rear as the patriarch of the party on the back of a mule. Two or three of the more enthusiastic spirits, under the intoxicating influence of the Dovedale scenery and not to be deterred by such commonplace matters as the flight of time and its consequences, prosecuted their rambles as far as Dove Holes and had to hurry back in hot haste, arriving at the hotel only just in time to make a scant and, it is feared, a very fragmentary meal before the departure of the waggonette for Ashbourne.

The excursion was a most enjoyable one, the only regrettable circumstance being the very large portion of the day taken up by railway travelling, and the consequent shortness of time available for photographic work; but the experiences of the day seemed to whet the appetite for a future raid on the lovely scenery of the locality, and several of the members expressed themselves strongly in favour of another excursion to the place next season, which, if possible, should be arranged to leave Manchester by an earlier train.

For some reason or other the Derby Photographic Society was only represented by two gentlemen, whom the Manchester members met in the Dale, and who joined the party at the hotel in taking tea.

The President, Mr. Atherton, Mr. Coote, Mr. McKellen, and Mr. Scott remained at the hotel to be in readiness for a field day on the Monday following, when some further work was done in Dovedale as well as at Ilam and Thorpe. The time, however, even of those who remained over Monday, was much too limited for the amount of work to be done. Dovedale itself for a distance of two miles is, of course, the gem of the Peak, but for many miles further up the valley the scenery is charming. In Narrowdale and Beresford Dale—redolent with associations of quaint old Izaak Walton and "his son," Charles Cotton—are to be found innumerable "peeps;" but nothing short of a three or four weeks' residence in the locality, and the most favourable weather, would suffice to accomplish all that can be done.

THE last of the season's outdoor meetings in connection with the above Society took place on Saturday, the 6th inst. About a dozen members and friends were present; but, unfortunately, a steady downpour of rain all the afternoon somewhat marred the enjoyment, and prevented a lavish use of the camera. Had it not been for the liveliness of some of the ladies the afternoon would have passed off very dull indeed. In a waggonette and under an awning of umbrellas the party left Alderly Edge *en route* for Capesthorne Hall. At Nether Alderley a halt was called, but neither the picturesque old mill or the many "bits" of black and white scattered about, nor even the ancient church, could tempt anyone to unlimber, so the order was given to "drive on."

At Capesthorne Hall—a fine brick and stone mansion of the Elizabethan period—the party took shelter in the spacious conservatory, where several plates were exposed, and many of the trees in the park and the extensive lakes excited the admiration of the members. These, however, like many other of Nature's pictures, had to be left without carrying away a duplicate. Astle Park, Chelford, was also on the programme; but this, likewise, had "to be continued in our next."

The prettiest picture, and one which found favour in the sight of all, was that of a tea-table laid out in the most *recherché* style at the "Trafford Arms," Alderley, and more plates were exposed and used on that picture than on any other during the afternoon.

Had it not been for the excessive and unrelenting rain this trip would, probably, have been one of the most pleasant and successful of the summer series. By the leader's characteristic judgment and foresight, everything had been so well planned and prearranged, and the route chosen was so continuously lined with picturesque beauty, that it is to be hoped Mr. Wade will repeat the excursion next season.

CHICAGO PHOTOGRAPHIC ASSOCIATION.

A REGULAR meeting was held at the Association Room, 229, State-street, on the evening of the 6th ult.,—Dr. H. D. Garrison, President, in the chair.

Mr. A. L. Henderson was proposed and elected for honorary membership.

The CHAIRMAN, in introducing Mr. Henderson to the Association, observed that he had no doubt the great majority of those present were more or less acquainted with him through his contributions to the English journals. There were few men who had done more to advance dry-plate photography, and the results of his researches and experiments had always been given freely to the world. Some of those present, who had attended the late convention for the revision of the constitution and by-laws, in Cincinnati, might perhaps be aware that Mr. Henderson had offered to demonstrate his method of emulsion-making before that Convention; but, through influences not exactly understood by the speaker, he was not allowed to say a word. There was a whisper in circulation to the effect that a prominent officer of the P. A. of A. was too much interested in a certain dry-plate factory to permit any matters relative to dry-plate making to be discussed, but as to that the speaker could not vouch. In dismissing the subject, he would remark that the Cincinnati meeting was the first photographic convention he had ever attended where *not one word was spoken about photography*. However, Cincinnati's loss was their gain, and, without taking up any more time, he would now introduce Mr. Henderson, of London, who would make an emulsion before them and answer any questions.

Mr. Henderson's remarks were as follow, much being in the form of questions and answers freely and courteously given.

Mr. A. L. HENDERSON:—Your Chairman is perfectly right in his statements about the Cincinnati Convention. I *did* suggest to Mr. Kent that if there was a gap to be filled up I should be most happy to occupy it with a practical illustration of emulsion-making; but let that pass. I have had the pleasure from time to time of publishing many little things in the English and continental journals, which have been appreciated, especially in France and Germany. The process which I shall demonstrate before you tonight is what is known as the cold emulsification process. It allows you to obtain readily almost any degree of sensitiveness that may be desired. It should be remarked here (although I suppose it is pretty generally understood) that the more sensitive the emulsion the less light you can use in preparing and developing your plates. Some time ago I myself offered a small money prize for a safe light for this purpose, but there were no competitors. They all said—"If you cannot devise such a light yourself, Mr. Henderson, it is useless to expect any one else to do it." I do not think that these gentlemen quite did themselves justice in taking this view of the case; but, at anyrate, I did not get my "safe light." About the best thing I have met with so far is a peculiar variety of paper called "canary medium." I have a piece of it here, which may be cut in little bits for distribution. I may say that it is astonishingly safe. A window three feet square covered with it, and lighted by a small gas jet behind, gives ample illumination for all purposes at a distance of four feet from the window. It is impossible to tell the colour of the paper by gaslight. It is a peculiar greenish-yellow, and is, I believe, a chromate of lead colour. You use it without oiling or other treatment.

Mr. BURNHAM: Can this medium be safely used when daylight is the illuminant?

Mr. HENDERSON: Daylight is such an uncertain quantity that it is difficult to answer that question directly. However, I should advise you to use the paper double in that case. I may observe that I do not use either daylight or gaslight myself, but a small kerosene lamp, giving a flame much smaller than a candle. The rapidity of an emulsion depends, amongst other things, on the quantity of gelatine used in the process of emulsification. A very small quantity is sufficient. I will take five grains in four ounces of water. By using ten grains a much finer deposit would be obtained, but the emulsion would also be much slower. The rapidity of the emulsion can also be regulated by varying the quantity of salts in proportion to the water. I am using here gelatine pure and simple, but in my own practice I use meta-gelatine prepared in this way:—Take 300 grains of gelatine, nine ounces of water, and one ounce of ammonia ('880); boil until the solution entirely loses its power of setting. This is then kept as a stock solution; for with the addition of a few drops of ammonia it will keep almost indefinitely. I dilute it for use as required. There are great advantages in thus having the liquid gelatine all ready for making your emulsion, instead of having to dissolve your gelatine as required. You thereby avoid the necessity for using heat at all during the formation of the sensitive bromide of silver. I keep this meta-gelatine for sale, put up in bottles under the name of "glueine." Well, I am now dissolving five grains of gelatine in four ounces of water by the aid of heat (Nelson's No. 1 gelatine). This done, I add three drachms of potassium bromide and two grains of potassium iodide. Let it dissolve. Next, I take four drachms of silver nitrate, divide it in two equal quantities and dissolve each separately in two ounces of water, or dissolve the whole in four ounces of water and divide the solution in two equal parts. A good deal depends on the form in which the silver bromide is formed to start with.

Professor HOUGH: How much more rapid than a wet collodion plate can you make an emulsion by this process?

Mr. HENDERSON: If you will define the rapidity of your wet plate I should be better able to answer that question.

Professor HOUGH: Well, take a neutral collodion and bath, and everything in the best possible condition for rapidity?

Mr. HENDERSON: I am certainly well within the mark in saying sixty times. If challenged I should have no hesitation in guaranteeing to make an emulsion one hundred times faster than your ideal wet plate. In England, however, we have dropped this kind of comparison as too indefinite, and all tests are referred to Warnerke's sensitometer.—Next, I take one drachm of carbonate of ammonia, and add it to one-half of the silver solution (that is, to two drachms of nitrate of silver dissolved in two ounces of water). This, of course, converts a part of the nitrate into carbonate of silver. I may mention here that the sensitiveness of the emulsion will depend, *inter alia*, on the proportion of the total quantity of silver nitrate thus converted. If I want a slow emulsion I only convert about one-quarter of it; if a *very* rapid one the whole. My reason for dividing the silver in two parts is to ensure that a definite quantity shall be converted. I would caution you to be careful that your carbonate of ammonia is pure, especially that it contains no chloride. Now I add liquid ammonia until the precipitate redissolves. This ammonia must be weaker than I have been accustomed to use, for it takes a great deal of it.

Mr. AIKEN: Why do you use carbonate instead of aqua ammonia?

Mr. HENDERSON: I think that question will be answered in the course of the demonstration, but I can answer it now. You would then get oxide instead of carbonate of silver, which would cause your emulsion to work foggy if the oxide was formed in the light.—Next, I mix the carbonate solution with the remaining half of the nitrate solution, and by means of this dropping bottle stir it in to the bromised gelatine. A light, flocculent deposit is the result. It is, perhaps, unnecessary to observe that this last operation must be performed in the dark room, while up to that point everything may be done in broad daylight. This done, we will add four drachms of gelatine, and place the jar containing the emulsion in this pot of hot water to dissolve it, stirring it all the time. You will see how, as the gelatine dissolves, it will break up the flocculent deposit. The temperature of the water in the pot should not be allowed to exceed 120° Fahr. It is important to use a vessel of a certain size and a definite quantity of water at a fixed temperature if you want uniform results. For this quantity of emulsion I should take three quarts of water, and heat it to 120° before putting in the emulsion; then, the gelatine being dissolved (with constant stirring, remember), the cover is put on and the whole business allowed to cool down. If the emulsion has not set at the end of three or four hours it would perhaps, in your climate, be advisable to use ice or other artificial means to make it do so.

Mr. AIKEN: Has the rapidity of cooling any effect on the sensitiveness of the resulting emulsion?

Mr. HENDERSON: I think not. You can make one thousand batches of plates by this process, and have them all exactly alike in sensitiveness. I asked Professor Haddon some time ago to make some experiments on the behaviour of silver bromide under ammonia treatment. He tested the matter under the microscope, and arrived at the conclusion that the smaller particles were dissolved, and the larger ones agglomerated into hexagonal masses. His conclusion was that the hexagonal form is the most sensitive condition of silver bromide. This gelatine (Heinrich's) is too hard to suit me, but, perhaps, for your climate it may be all right. It has been my experience that the softer the gelatine the finer the quality of the resulting negative. I will pass around some of this emulsion on pieces of glass, in order that you may judge the colour and structure of it. Now, gentlemen, I have shown you the principle and method of working of the cold emulsification process. If there are any points not exactly clear I shall be pleased to answer any questions.

Mr. Hesler: Does the speed of drying affect the sensitiveness and clearness of the plates?

Mr. Henderson: Our English climate is very variable, and at first I found that a change of temperature or of the hygroscopic condition of the air during drying would cause circular marks on the plates. This I have overcome by adding a little thymol dissolved in alcohol, just before filtering the emulsion for use. Its action is simply to prevent decomposition. My plates have always been dried in an open room—not by artificial means.

Prof. Hough: Did I understand you to say that you can make a dozen successive emulsions exactly alike?

Mr. Henderson: Yes, by always adhering closely to the same quantities and temperatures.

Prof. Hough: About what difference in rapidity would result from using ten grains of gelatine instead of five?

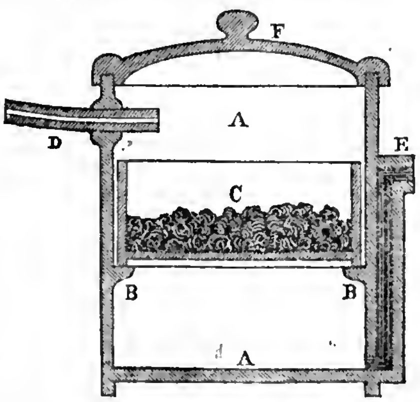
Mr. Henderson: You would reduce the speed more than one-half. In a general way, I consider it unwise to use a large quantity of gelatine as a retarder, and then accelerate by means of heat. Moreover, the less gelatine the silver comes in contact with the better; for the combination of the silver nitrate and bromide is not instantaneous, so that even if you have an excess of the latter the silver has some chance to combine with the gelatine. For this, among other things, I prefer to emulsify with meta-gelatine, because I believe this is all removed in the washing, and the gelatine subsequently added does not come in contact with free nitrate at all.

Prof. Hough: Suppose you used half the total quantity of gelatine to emulsify with?

Mr. Henderson: The ratio of speed would not be the same in this case; it is a diminishing ratio as the quantity of gelatine increases. Probably, taking the five-grain emulsion as twenty Warnerke, the 120-grain one would read about ten. It may be necessary to explain here that the numbers on Warnerke's sensitometer do not represent the ratio of speed, but every three figures about double the speed; thus, thirteen would be twice as rapid as ten; sixteen, four times; nineteen, eight times; twenty-one, sixteen times, &c. Warnerke's sensitometer consists of a plate of glass, on which are superposed, step fashion, twenty-five layers of carbon tissue, of equal thickness. The plate to be tested is placed behind it, and the source of light is a tablet coated with phosphorescent sulphide of calcium, excited by burning a piece of magnesium ribbon. It has been proved by experience that a certain length of ribbon is sufficient to raise the tablet to its greatest luminosity. After excitation the tablet is allowed one minute's rest before being used to test plates, it having been discovered that a very rapid falling off in luminosity occurs during the first few seconds, but that after a minute the decrease is so slow that it may be disregarded.

A Member: Please give us a little information about washing.

Mr. Henderson: As to the time required for washing: much will depend on the temperature of the washing water; but it is a good plan always to keep on the safe side. After my emulsion is set I put it in a vulcanite cylinder with both ends open. Over one end is fastened a sieve of copper wire—I believe about No. 16 mesh; while through the other an ebonite plunger is introduced, expelling the emulsion in shreds. The emulsion thus broken up is placed in a washing apparatus, constructed as follows:—A is a vessel of wood or stoneware (mine is of the latter material, by Doulton, of Lambeth) with a ledge, B, round its interior at about one-third its height from the bottom. On this ledge rests a fine hair sieve, C, in which the broken-up emulsion is placed. Above the top of this sieve a water supply pipe, D, enters; while at the bottom it is provided with a bent outlet, E, of such height that the water level is preserved above the top of the emulsion in the sieve. F is a light-tight cover. You must be careful to keep the whole of the emulsion under water during the operation of washing. I have traced some of my own failures to allowing some portion of it to adhere to the side of the sieve where the water did not reach it.



When washed and redissolved your emulsion should measure about fifteen ounces; if less, make it up to this quantity. Asked by a member as to the quantity of thymol necessary, Mr. Henderson replied that for this quantity of emulsion seven or eight grains dissolved in half-an-ounce of alcohol would be ample. He had found no injurious action on the emulsion from the copper wire; but the wire itself was rapidly corroded by the ammonio-nitrate salts, and he would recommend that it be silver-plated.

Dr. Garrison: Have you tried the addition of bichromate of potash to the emulsion before washing?

Mr. Henderson: I do not see any advantage in it. It will remove green fog, to be sure, but it changes it into grey fog, which is worse.

Mr. Aiken: What substratum do you recommend?

Mr. Henderson: I never use any. Mr. A. Cowan, of London, tried some experiments on the addition of various quantities of chrome alum to the emulsion and found no difference in speed. If there were any difference in brilliancy it was in favour of the emulsion containing the largest percentage of chrome alum. I have not used formic acid, but it is used by some makers to prevent frilling. Frilling, by the way, is generally owing to decomposition of the gelatine, and if proper care be taken not to make the emulsion too hot, and not to remelt it too often, there should be no trouble on this point.

Mr. Hesler: You promised to say something about iodide in emulsions.

Mr. Henderson: If you use much more than I have here—two grains of iodide to three drachms of bromide—you will slow your emulsion considerably. However, the more gelatine your emulsion contains in proportion to silver the more iodide you can use without perceptibly slowing your plate. The reason is this: iodide makes a yellow film more difficult for the light to penetrate; but the larger the proportion of gelatine the more transparent is the film, so that the yellow tinge is not so obstructive. In landscape work a pretty thick (opaque) film is an advantage as a safeguard against halation, and it allows more latitude in exposure.

Mr. Aiken: Do you find any advantage from the use of a chloride?

Mr. Henderson: None whatever. There is a question whether chloride can exist for any length of time in presence of free bromide. I will relate a strange experience. Mr. Cadett gave me a boiling formula. By boiling fifteen minutes he found that he got a certain speed. Boiling forty-five minutes gave him a much greater rapidity, but beyond that he could get no benefit from prolonging the cooking. I tried his formula, and could only get the speed he attained in fifteen minutes by continuing the boiling two hours. Mr. Cadett's plates, by his formula, fixed quicker than those made by mine, although they contained about ten times the amount of iodide. Mr. Cadett was under the impression that the iodide was precipitated and filtered out; but from experiments I made I found that this was not so, and I have come to the conclusion that, by prolonging emulsification at a high temperature, iodide of silver cannot exist in presence of free bromide. The cold emulsifisation gives much more sensitiveness than boiling. A boiling emulsion may give as high a sensitometer number as an ammonia one, but in the former several figures will dissolve out in fixing; that is to say, they will not develope to printing strength.

Dr. Garrison: What developer do you recommend for these plates?

Mr. Henderson: They can be worked with any developer, but mine is generally prepared as follows:—Take one ounce of pyro., half-an-ounce of potassium bromide, fifteen ounces of water, and ten minims of nitric acid for stock solution. For use, dilute this down with water to two grains of pyro. per ounce, and add to each ounce two minims of liq. ammonia (·880). I find no advantage in sulphite of soda.

Mr. Aiken: Do I understand that your stock solution of meta-gelatine is thirty grains to an ounce?

Mr. Henderson: Yes; gelatine is boiled until it decomposes. The ammonia is added to accelerate the action. Prolonged boiling without ammonia would answer the same purpose. I prefer Nelson's No. 1 for emulsifying.

Mr. Edgeworth: I believe you claim to make an emulsion with less silver than others.

Mr. Henderson: I have used as little as one grain per ounce and obtained fairly rapid plates with good density. For opals or gelatino-bromide paper I think this is just what is wanted. A heavy emulsion is fatal to brilliancy in this case. I have made thirty-seven ounces of emulsion with thirty grains of silver, but I do not recommend such extreme economy. I can, however, make a very good emulsion with the same quantities of salts I have used here, increasing gelatine and water to bring it up to thirty ounces.

Mr. Burnham asked some questions as to the use of canary medium in daylight.

Mr. Henderson replied that it was always advisable to use as little light as possible. Nearly all the trouble with fogging, so often complained of with rapid plates, resulted from using too much light in handling them. He did not believe in chemical fog at all.

Mr. Greene: How much emulsion would you allow for an 8×10 plate?

Mr. Henderson: I am more familiar with some other sizes. For instance: fifteen ounces of emulsion prepared according to the formula I have used tonight should coat thirty-six $8\frac{1}{2} \times 6\frac{1}{2}$ plates, or a gross of quarters. The more rapid the emulsion, however, the thicker your plates must be coated, as a protection against halation, for the reason that a blue film is so much more readily penetrated by actinic rays than an orange one

Professor Hough: Do you consider a very rapid plate as good as a slow one for general use?

Mr. Henderson: Yes; but it requires much more skill to develope it. Colonel Stuart Wortley stated the case concisely when he said that he could teach anyone to make an emulsion, but that to develope a plate was a science only to be acquired by long practice. If I were making plates for the trade and wished to make money I do not think I would put on the market anything more rapid than a sixteen Warnerke—about the average sensitiveness of a Britannia or Wratten and Wainwright plate. Such plates as these anyone can develope. Of course, if parties wanted more rapid plates, and I knew them to be capable of handling them, I would supply them, but should not consider it policy to put them on the market indiscriminately. He (Mr. Hendeeson) now passed round for examination some gelatino-chloride prints on opal glass, which were much admired for their brilliancy and warm reddish tone. He explained that the process was neither patented nor secret, but consisted simply in coating the plates with a chloride, instead of a bromide, emulsion, and printing by contact similarly to the old collodio-bromide process—no development. Prints can be toned to any colour desired. The following is the formula:—

Hard gelatine (dissolved in one and a-half ounce of water)	80 grains.
Silver nitrate (in half-an-ounce of water)	75 ,,
Dry sodium chloride	21 ,,
Potassium citrate	21 ,,
Water	½ ounce.

Warm and dissolve.

Warm the solution of silver and gently pour into gelatine; then add the sodium and citrate, also warm, stirring all the time. Pour into a dish to set. Work in a yellow light. Wash in the ordinary way, but keep everything very cool, as this emulsion is very thin. Then melt up and add two drachms of alcohol containing three grains of salicylic acid and one grain of chrome alum in a little warm water: filter, and coat. You will find the emulsion almost as thin as water. If great contrast is wanted work it thicker and the reverse for softness. The emulsion will not keep, so make small batches as required, and use the plates as soon as you conveniently can, for they are prone to turn yellow. Tone in a borax bath after a thorough washing, fix in hypo. (twenty per cent.) for at least ten or fifteen minutes, wash well, and give a bath of alum. These plates may be printed in the ordinary frames without difficulty. Push both negative and opal against one side and end of the frame—that is, into one corner. You may examine as often as you please.

Mr. Edgeworth: As the question of substratum has been raised it may, perhaps, interest some of those present to state that nearly all the large dry-plate factories in this country have abandoned the use of any substratum, and now simply polish their glass on a cotton buffing wheel running at a very high speed. Mr. Eastman uses a species of whiting on the buffing wheel, but I think the others use nothing whatever.

Mr. Henderson: One plate-maker in London, who has unusually clean water to work with, cleans his glass with soda and water, then with clean water and a rubber sponge, finishing with a rinse under the tap, and dries his glass in a cabinet over a Bunsen burner. I have a glass-dryer at home, completed just before I left; but I have not thoroughly tested it yet. If I used any substratum at all it would be silicate of potash. In making plates solely for my own use I have never found such a thing necessary. Possibly, if making for the trade, I might use a substratum.

Mr. Douglass, in moving a vote of thanks to Mr. Henderson, said he understood that that gentleman had remained at some little personal inconvenience in order to be present at this meeting, and he was sure everyone present felt under a great obligation to him.

The motion was carried unanimously, after which the meeting was adjourned.—*Phot. Times.*

Correspondence.

A SODA DEVELOPER.

To the Editors.

Gentlemen,—If Mr. E. Dunmore has not tried the following excellent modification of the soda developer I think he will find it works most satisfactorily. It was given to me by a friend—Dr. Carter Browne—who tells me he "spotted it" in a late number of the *English Mechanic*. I find it most useful in all cases where the necessary exposure can be pretty accurately determined, as, for instance, in interiors and copying; at the same time it will admit of considerable modification in cases of under- or over-exposure.

The colour of the negative is not the usual "bottle green," as it has been not inaptly termed, but a purple black, similar to that obtained with ferrous oxalate. The shadows are perfectly clear, without any veil whatever, and the range of tone everything that could be desired. As a standard developer it possesses the great advantage of *stability*, whereas each time the ammonia bottle is uncorked there is an undoubted loss of strength, and consequent weakening of the developer.

I give the formula as I received it from Dr. Brown, and trust that others will be as pleased with it as I have been:—

No. 1.

Sodic sulphite	4 ounces.
Hot water	10 ,,

When dissolved and cool, add four ounces of sulphurous acid; then add one ounce of dry pyro.

No. 2.

Washing soda	3½ ounces.
Sodic sulphite	¾ ounce.
Water	64 ounces.

To develope: use one drachm of No. 1 to each ounce of No. 2.—I am, yours, &c., L. Macdona.

Cheadle Rectory, Cheshire, September 10, 1884.

N.B.—Place the negative in the alum bath after development. If this be omitted the purple-black colour will not be obtained.

[Is there no bromide included in the above formula?—Eds.]

To the Editors.

Gentlemen,—Bachelors' wives and old maids' children are well known to be the most perfect specimens of humanity. It seems from correspondence that it is the same with photographers' developers. I have one which I love so much that any gelatine plate that would not behave in a most becoming manner towards it I would at once condemn and discard.

The way I proceed to develope with this developer is as follows:—I make saturated solutions of carbonate of potash, sulphite of soda, and washing soda. These I name 1, 2, 3, which means—take

1 part of carbonate of potash.
2 parts of sulphite of soda.
3 parts of washing soda.

To these add forty-eight grains of bromide of potassium dissolved in eighteen parts of water, and label this "soda solution." Now dissolve a-quarter of an ounce of citric acid in thirty ounces of water; add this to one ounce of pyrogallic acid, and label this "pyro. solution."

To develope a half-plate take—

Pyro. solution	2 drachms.
Soda solution	*quant. suff.*

I never soak the plate with water previous to developing, as it is one cause of frilling.

Anyone who tries this developer I feel sure will value it as I do. It has every virtue, and none of the faults of the soda or potash used alone.—I am, yours, &c., Henry Law.

30, *Waterloo-street, Leicester, September* 6, 1884.

[Our correspondent will, upon reperusal, discover that the above formula is quite indefinite, owing to "parts" being alternated with definite quantities, such as "grains." To prove of real benefit the quantities should be definitely expressed. We shall be glad to receive the amended formula.—Eds.]

"EDWARDS'S MACHINE FOR COATING PLATES."

To the Editors.

Gentlemen,—I have read and contributed to your Journal since its commencement, but I believe such a letter as that of Mr. B. J. Edwards has never previously appeared. It commences with a misstatement.

Mr. Edwards says I object to his patent on the ground that "certain parts" have been previously used. This is incorrect. I object on the ground that the *entire machine* has been in manufacturing use for years, and my statement has received complete corroboration in your columns. I say Mr. Edwards is not the inventor at all, and has no right to take out a patent and thus exclude the photographic community from using it if they wish.

A correspondent reminds your readers that this is not the first time Mr. Edwards has done this, and cites the "patent grooved plate box" as an instance. The use of these boxes has been much hindered from the belief that Mr. Edwards held a patent, whereas they can be ordered in the trade just the same as any other box.

Not content with taking out a patent for an already-existing machine, he seeks to cast discredit on methods of coating plates by machinery, as at present known, as being remarkable for "well-known defects." Well, gentlemen, I can say from my personal knowledge that some of the largest manufacturers of dry plates have been employing for years past machine-coating with complete success. The late Dr. Monckhoven devised an exceedingly-successful machine which has been in use for years at the great Belgian manufactory, and the simplicity of which would astonish Mr. B. J. Edwards. Again: my own firm have used since August, 1879, machine-coating with perfect success, some of the machines having run eight hours a day for nearly five years with scarcely any intermission. This system of coating is also adopted by the Compagnie Anglaise, who work our method at Rouen.

By what right, then, does Mr. Edwards make these disparaging statements, of the truth of which he has no kind of evidence? It is simply to bolster up his intention to grant licences for his so-called "patent." He has no right whatever, either in equity or any other way, to attempt to obtain any such payment, the machinery being open to the whole world. He threatens to "stringently maintain" his rights. No doubt lawyers can readily be found to threaten and serve processes; they know their costs will be paid. But no one need have any fear of these threats.

I sum up the whole matter by saying that if I had not seen the subject in print it would have seemed incredible that anyone could attempt such a thing as Mr. Edwards has.—I am, yours, &c., Samuel Fry.

Kingston-on-Thames, September 8, 1884.

To the Editors.

Gentlemen,—Surely your correspondent who signs himself "A Patent Agent" allows his zeal in advocating the validity of Mr. B. J. Edwards's plate-coating patent to carry him a little too far. He says that in order to contest the patent "it will not only be necessary to show that the apparatus as it now exists *as a whole* has been previously in use, but that it has been in use for coating plates with gelatine emulsion."

According to this doctrine a man desirous of patenting a wheel may take the spokes invented by one man, the tire of a second, and the hub of a third, and patent the use of them in conjunction; and, not only so, but if the wheel as a whole had already been in use for an omnibus, he could patent its application to a cab. If such be really the state of the law the sooner it is altered the better.—I am, yours, &c., Looker-on.

September 9, 1884.

THE ETHOXO LIGHT AND GAS EXPLOSIONS.

To the Editors.

Gentlemen,—In reply to Mr. H. Ives's letter, in your issue of August 29th, I may say I admit his *prior publication* of a porous filling for ether chambers, but certainly dispute his prior invention. I have never attempted to eulogise my own invention, preferring to let others do that. But if I am to believe what a countryman of his tells me "Ives's generator" is not the success the inventor would have us to believe, and from reading a catalogue from America, which I recently saw, I shall certainly come to the same conclusion, for there were instructions how to act in case the generator took fire.

As to its being made and sold at a price, that is no criterion of merit. The *original* chamber anyone may make, as *I gave the world* the benefit of my discovery in the pages of THE BRITISH JOURNAL OF PHOTOGRAPHY in the year 1881, but not of the present form.

Explosions do not occur where everything is properly managed; it is where there is *mismanagement* that we have to deplore accidents; and from these there is no protection, as far as I can gather, in Mr. Ives's generator. In my own lanterns I do not use pumice chambers, and never have any "popping" in them.—I am, yours, &c., W. BROUGHTON.

Eccles, Manchester, September 4, 1884.

Notes and Queries.

B. FLETCHER is informed that the best and most convenient cloth for cleaning a lens is (if he will excuse the Hibernicism) a soft wash leather. This is better than the silk handkerchief to which he alludes.

"CAN you supply me with the late Mr. H. Negretti's formula for printing stereoscopic transparencies by the albumen process?—GEO. B. ROBERTSON."——In reply: The formula recommended by Mr. Negretti consisted of a hundred parts of albumen, diluted with twenty parts of water in which one part of iodide of ammonium had been dissolved. The sensitising bath was a ten-per-cent. one, containing a proportion of glacial acetic acid equal to the silver. A saturated solution of gallic acid, used warm, and having a few drops of the sensitising bath added, formed the developer. From this it will be seen that several changes and improvements have been made since this formula was published.

PH. D. says that he requires a very thick bi-convex lens of about four or five inches diameter, and he cannot obtain glass of the requisite thickness without incurring more expense than the work can afford. He asks if we can afford him any hint by which to avoid this difficulty.——To this we reply that the best way to proceed is to obtain two discs of glass of the greatest thickness procurable, grind them as plano-convex lenses, and then cement the flat sides together. If "Ph. D." be not compelled to adopt any definite radius of curvature we would advise him to obtain from an optician who makes a specialty of lantern appliances a pair of unmounted plano-convex condensers and combine these with cement.

"I HAVE some very thin and transparent gelatine plates of my own preparation, made for a special purpose (photomicroscopy) and I occasionally find a luminous margin or halo round light portions which adjoin dark parts. Is there any remedy for this?—ALPHA."——In reply: Our correspondent will prevent this halation by sponging over the backs of his plates with either the following or a mixture of a similar character:—

Burnt sienna	100 grains.
Dextrine	30 ,,
Glycerine	2 minims.
Water	Enough to form a pasty mass.

After exposure remove this backing by a wet sponge, and when the image is developed there will not be the slightest appearance of halation.

F. writes:—"Referring to your remarks about photo-crayon, and a method by which the enlargements can be prevented from fading, I shall feel greatly indebted if you will let me know by what means this can be done. I have carefully and closely followed Sarony's instructions, and as my pictures changed tone after a time I concluded that the fault must have lain with myself rather than with the process. I may say that I eventually discontinued making them on account of their fading."——We reply: The whole secret consists in a total abandonment of mercury as the toning agent and substituting for it gold, platinum, or some other reliable agent. Uranium produces tones less cold than the platinum or gold, and equally durable, so far as our experience has gone. It is not difficult to produce a rich purple tone by development alone without having recourse to any toning at all.

"WOULD you kindly oblige me, if possible, with a formula for photograpic crystal varnish? My various books of receipts give a formula for a crystal varnish, namely, equal parts of Canada balsam and turpentine; but I doubt much if this is the proper photographic article. I require some for immediate use, and cannot get any in the town, and, what is more strange still, I have never come across any formula for crystal varnish in the Journal. Although I have perused many volumes, not a single formula can I find in the ALMANACS. Twenty years ago I used crystal varnish (I think) for glass positives, and it was certainly not a turpentine varnish. My present purpose is—firstly, by the addition of white wax to make an imitation ground glass for stereo. transparencies; and, secondly, to varnish the *film* side of some glass positives recently taken, so that this varnish shall resist the—or rather any—action of Bates's black varnish when the outline of the portrait is filled up with the latter. This, I think, crystal varnish will do. This is a very pretty way of finishing glass positives, for the portrait then appears to have been taken on ivory, if white, or cream paper be placed beneath.—W. F. STEVENS."——In reply: We know of at least two classes of crystal varnish—one consisting of a solution of Canada balsam in turpentine, and the other a benzole solution of gum dammar. The latter will probably answer the purpose of our correspondent. With regard to the method of finishing glass positives referred to: if we are not mistaken it was extensively practised by Mr. John Urie, of Glasgow, a-quarter of a century ago. We think that he also obtained a patent for the method in question. We are not at present quite clear whether it was the film side or the glass side to which the black varnish was applied.

Exchange Column.

Answers to Correspondents.

☞ *Correspondents should never write on both sides of the paper.*

NOTICE.—*Each Correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a* NOM DE PLUME *as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.*

PHOTOGRAPH REGISTERED.—

Thomas Forrest, Cambrian Studio, Pontypridd.—*Photograph of the Town of Pontypridd.*

AMATEUR.—We presume so, though we have not really tried it. Why not make the experiment yourself?

C. B.—By all means employ a slow bromide plate, and one that will yield a dense image. The other plates are by no means so suitable for your purpose.

ERRATUM.—In the article on page 561, twenty-four lines from the bottom of first column, for "slightly *focussing* with ammonia," &c., *read* "flushing," or rinsing.

JOSEPH HOLMES.—The prepared paper is not an article of commerce in this country. It is quite possible that you can procure it through Dr. Liesegang, of Dusseldorf.

SILVER.—1. There is no silver in the waste developing solution.—2. A very small proportion of the deposit only is silver, the major portion being oxidised pyrogallic acid.—3. No.

GEO. SMITH.—There appears to be something wrong in the figures somewhere. You had better write to the agents for the sale of the instruments in this country for an explanation.

J. C.—We presume the label will be copyright if the registration were legally effected. If you have any doubt on the subject you had better consult a respectable solicitor before commencing litigation.

J. G.—1. You will find a table of the solubility of the salts in question on page 252 of our ALMANAC for the current year.—2. We should surmise the remedy would be efficacious, but the only way to test it definitely is to make the experiment.

J. E. Z.—The negative appears so very much over-exposed that we fear you will not succeed in bringing it up to sufficient density to yield satisfactory prints. Try the effect of sulphite of soda as a blackening agent, instead of the hyposulphite.

A. E. D.—1. The cause of the fog in intensifying the negatives was due to your insufficient washing between the separate operations.—2. A certain amount of oxidation will always take place. However, filter the solution and then try its efficacy by developing a plate.

A. G. Hopkins.—1. The fittings are generally made to the order of the camera-makers, most of whom have their own particular pattern. Perhaps some of the camera-makers will supply what you require.—2. Lampblack mixed with white hard varnish, thinned with methylated alcohol, is the best material with which to blacken the inside of the camera.

O. Evans.—1. The camera is much too short for the purpose.—2. You will find a table giving the length required in enlarging and reducing in our Almanac for the current year, page 261.—3. Better try the experiment. We have not done so. As a rule, you will find the formula issued by the maker of the plates more suitable for his particular plates than that of any other maker.

Patience Passe Science.—You had better provide yourself with two lenses. Those marked Nos. 1 and 4 on your list you would find most generally useful. If you politely explain to the Customs officials that the boxes contain photographic plates which would be spoilt by exposure to light, we imagine you will experience no difficulty, particularly if you offer to show them in a non-actinic light.

Amateur (Liverpool).—1. You may avoid the prints adhering in future by treating the glass either with powdered talc or bees'-wax.—2. The bicarbonate of soda toning bath should give you the tones you desire—that is, if the negative be a rich and vigorous one and the paper suitable. Remember, the tones of the prints very much depend upon the quality of the negative. The prints are returned as requested.

Bordesley.—We have no means of knowing with certainty if the work in question be copyright except by searching the records at Stationers' Hall. But we have not the slightest doubt in our own mind that it is, as no one would think of publishing such a work without securing copyright. Of course if you copy the picture, and it possesses copyright, you will render yourself liable to a penalty of ten pounds for every copy you sell.

Laurence.—We fear, as the ends of the negatives are so totally different in character and density, that you will not be successful in joining the prints, or combining the negatives, so as to get a panorama without the joins being painfully conspicuous. If you carefully re-read the articles on combination printing you will find one or two plans which may prove useful, or at least materially assist you, in this particular instance. From the prints it is clear that much will depend upon your skill in retouching the different negatives, so as to equalise their density at the parts to be joined.

E. S. D.—1. The prints produced on gelatino-bromide paper will be different in appearance to those made on albumenised paper.—2. The tone does not depend upon the burnishing.—3. If your negatives are inferior it will be impossible for you to get rich-toned prints from them.—4. Not useless, but less energetic in action.—5. All things being equal the results would be the same.—6. The only way of settling the point is by trying the lens and judging its quality.—7. It would be useless to devote space in these columns to describing what may be found in any elementary manual.

Received.—E. H. Farmer; Archer Clarke; H. E. Harris; "R. S.;" "X X X;" "W. M."

Drop Shutters.—Drop shutters and instantaneous shutters are common enough as applied to lenses of somewhat small dimensions; but it is the exception rather than the rule for any one to possess one of these appliances suitable for being employed with a lens having a diameter of from three to five inches. Here is a method which we can recommend from experience as being easily adapted for utilising large lenses in taking instantaneous views; at anyrate, it is sufficiently rapid to take pedestrians and street traffic under such circumstances as enable the moving figures to bear examination with a magnifying glass of moderate power. Provide two caps for the lens. These may be made of pasteboard or cloth. Provide also two squares of stiff pasteboard considerably larger than the front of the lens, or (say) seven by eight inches, which is the size we employ. Fix a cap to the centre of each of these. Now, when the camera is directed toward the object to be taken the lens must be capped by one of these squares, the right hand being relegated to this use. The left hand must hold the second capped square in such a way that it will be higher than its fellow to the extent of four or five inches, this forming a degree of separation sufficient for every purpose. The exposure is made by gently withdrawing the cap and quickly moving the covering square downward, the second covering-piece being simultaneously moved downward by the left hand, which works consentaneously with the right. The cap on the second square now replaces that by which the lens was previously covered. No one can form any idea of the rapidity and ease with which an exposure can be made by this method unless it were tried; still some conception may be had of it by taking hold of two pieces of card, one with each hand, and keeping a space of a few inches between them, giving them a quick downward descent, until one occupies the place of the other. The rapidity much exceeds that of a simple drop-shutter actuated by gravity. If desired, both pieces may be attached to each other, or even one card may be made to answer by having a large square aperture cut in it, ample space being left for attaching the caps.—*Photographic Times.*

New Cards.—We have received from Messrs. Marion and Co. samples of their new designs for appointment cards. These are tastefully designed and printed in three colours, presenting a chaste and ornamental appearance.

Photographic Club.—At the forthcoming meeting of this Club, at Anderton's Hotel, Fleet-street, on Wednesday next, the 17th inst., the subject for discussion will be—*On Mountants.*—The Saturday afternoon outing will be at Hale End, leaving Liverpool-street Station at 2.2 p.m.

Portrait Painting in the Provinces.—The Merthyr *Express* speaks in high terms of a life-size portrait in oils of a lady of local celebrity and her daughter displayed in the window of Messrs. Harris, Son, and Co., artists, 88, High-street, Merthyr, just off the easel of Mr. Geo. F. Harris. It is characterised as being the highest effort in local portrait painting which the *Express* has seen for many years.

An Improved Egg-Beater.—Various means have from time to time been devised for beating albumen into a froth. We have received from Messrs. M'Nicol and Walsh, of Manchester, a specimen of their "climax mixer," which consists of a tin cylindrical vessel wherein works, through an aperture in a closely-fitting cover, a piston rod that actuates pistons attached thereto, and which are pierced with slots in such a manner as when quickly moved up and down among the albumen converts this latter into a frothy mass. This little instrument will prove useful to photographers and others.

Destruction of a Photographic Studio by Fire.—On Wednesday evening last week a fire broke out in a detached studio belonging to Mr. Whitehead, of 4, Pembridge-villas, East Acton, W. The building was 18 feet × 8 feet in circumference, and contained photographic apparatus and other valuable articles, which were all destroyed, the building being, in fact, gutted in a very short space of time. The damage is roughly estimated at £100. Mr. Whitehead believes the fire to have been caused by the accidental ignition of some drapery from a paraffine lamp.—*Acton Gazette.*

The Addition of Blue to Collodion.—Herr G. P. A. Garjeanne, of Amersfoort, says he has found that the addition of a blue dye to collodion considerably increased its sensitiveness. He had a remainder of collodion prepared according to the following formula:—

Ether	200 parts,
Alcohol	200 ,,
Cotton	4 ,,
Iodide of ammonium	2 ,,
Iodide of cadmium	2 ,,
Bromide of cadmium	1 part,

and a trace of nitric acid.

The collodion had become golden-yellow and was turning red; it worked slowly and hard. He stained it with Hofmann's violet BB (an aniline colour), after which the negatives became much richer and the sensitiveness was greatly increased. He then prepared another collodion—

Ether	200 parts,
Alcohol	200 ,,
Cotton	4 ,,
Iodide of cadmium	3 ,,
Pulverised bromide of potassium dissolved in a few drops of water	2 ,,

and stained it with methyl-violet. With a poor single lens and this collodion he took photographs with an exposure of five seconds in the shade, and almost instantaneously in the full sunlight. He, therefore, asks whether greater sensitiveness could not be imparted to collodio-bromide of silver by using a blue stain.—*Archiv.*

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician,
For the Week ending September 10, 1884.
These Observations are Taken at 8.30 a.m.

CONTENTS.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1272. Vol. XXXI.—SEPTEMBER 19, 1884.

SULPHUROUS ACID AND THE SULPHITES OF SODA.

The perusal of the Rev. L. Macdona's formula for a soda developer in our last issue raises once more the question of how best to utilise the advantages derivable from sulphurous acid as a preservative of the pyro. solution and a preventive of pyro. stain. That sulphite of soda has secured a permanent position amongst the photographer's list of chemicals cannot now be denied, though there are still some who dispute its efficacy, and others again who insist that it is absolutely detrimental. In the course of the present article we shall attempt to show where these discrepancies may, perhaps, arise.

The history of this application of sulphite of soda may be said to date back as far as 1877, when in an article on the late M. Sammann's "hydrosulphite" developer (vol. xxiv., p. 26) we pointed out the peculiarity exhibited by that solution, viz, that, however long it might remain exposed to the air, and however much discoloured it might become, it remained clear and free from sediment. In connection with collodion films this was a matter of minor importance, and it was only on the introduction of gelatine plates and the advent of the new trouble—pyro. stain—that the peculiar action of sulphurous acid assumed a special value. Mr. H. B. Berkeley was the first to recognise this, and in our Almanac, some three or four years ago, published a formula for development in which sulphite of soda figured. Subsequently Mr. J. Y. McLellan recommended sulphurous acid itself as being preferable on account of its exercising no slowing action upon development. The alleged existence of this latter fault appears to be the chief, if not only, argument brought to bear against the employment of the sulphite.

Such extremely-divergent opinions have been expressed on this point that it seems at first sight scarcely possible to reconcile them; and yet, upon inquiring closely into the matter, much of the discrepancy is explainable. Sodic sulphite, as our readers are well aware, is an extremely unstable salt, changing rapidly to sulphate by absorption of oxygen from the atmosphere. Sodic sulph*ite* and sulphurous acid are most powerful reducing agents, and, as such, aids to development—a fact which we first pointed out in 1877, in the article already referred to, when we showed that either the neutral or acid sodium sulphites, in conjunction with pyro., were capable of development. More recently—within the last few months—we have gone more fully into the matter. Sodic sulph*ate*, on the other hand, as first pointed out by Mr. Berkeley, though apparently neutral in its reactions, exercises a powerful restraining action upon alkaline development; and here we have the key to the secret of the discrepancies to which we have alluded.

Thus, given a new and good sample of sulphite, we shall have the maximum of preservative action without any restraining—possibly with an actual acceleration or increase—of development. However, as the sulphite becomes oxidised not only is its beneficial effect lowered, but an injurious restraining action is set up; and it is easily conceived that with a badly-oxidised sample the balance may be strongly in the latter direction, and consequently against the use of sulphite.

That the alleged slowing action of the sulphite is usually attributable to the employment of impure samples is, we think, proved by the fact that where such complaints have been made they have generally been accompanied by another—that the salt will not dissolve to the extent given in the various formulæ. Now, sodic sulphite is a very soluble salt, while the sulphate is much less so; consequently, as the mass of sulphite becomes oxidised it becomes less soluble—that is to say, it requires a larger proportion of water to dissolve it.

It may be remarked incidentally here that, in using the sulphite of soda, the method usually recommended of making a saturated solution is far preferable to that given with some formulæ of weighing out a definite quantity. The following considerations will make this plain. Suppose, for example, we are using a sample of sulphite which has become oxidised to the extent of twenty-five per cent. If we weigh out the correct quantity to make a theoretically-saturated solution we shall have it really only three-quarters saturated, whereas by allowing the water to act upon an excess of the crystals it will become saturated both with sulphite and sulphate. In that case, though the preservative action of the solution will be at its maximum, so also, probably, will be the restraining power of the sulphate.

Looking at the uncertainties which surround the use of sodic sulphite the recommendation to substitute sulphurous acid seems a good one; but unfortunately matters are not very greatly improved for the majority in that case. Sulphurous acid, or rather the solution of the gas which goes by that name, is quite as variable—in strength at least—as the sodic sulphite, and as the ordinary source of supply is in many cases a country chemist the article obtained is not likely to be of a very definite character. At its best the commercial article is but a feeble solution, the strongest obtainable containing less than ten per cent. of real acid. In the majority of samples from commercial sources we have examined the proportion has been less than four per cent. A freshly-saturated solution made specially for the purpose of testing showed barely nine per cent. It is clear, then, that except under most favourable conditions the use of sulphurous acid presents little chance of securing certainty of result; but it has at least one advantage in the absence of restraining power: though it may deteriorate in strength the falling off is not accompanied in inverse ratio by an increasing slowing action. We are leaving out of the calculation, as of no practical moment, the gradual conversion into sulphuric acid. This is not likely to produce any appreciable effect.

The acid sulphite or bisulphite of soda offers another alternative. This, though an even less stable compound than the neutral salt, contains a much larger proportion of sulphurous anhydride, and is at the same time readily soluble. It is thus possible to prepare a more concentrated solution. We are not prepared to say what are the precise changes that proceed during the process of oxidation but *prima facie* it would seem that so long as the bisulphite gives evidence of containing free acid its efficacy should be above suspicion. From the looseness of combination of its elements it is probable that the first change is a reduction to the state of neutral sulphite, in which case so long as the salt smells of sulphurous acid we know that it is in a condition fit for use. On the other hand, if the formation of sulphate (and of sulphuric acid) proceed as rapidly as in the case of the neutral sulphite, the smell of sulphurous acid is little more than evidence of decomposition, and the bisulphite is of less value than the neutral salt.

It must be borne in mind that when the free acid or the bisulphite is employed an extra allowance of alkali must be made in the developer.

As regards obtaining a supply of the bisulphite, there need be no more difficulty than in the case of the neutral salt, and the price is about the same. In these days, if any difficulty exist in obtaining a supply of chemicals, in even the remotest country places, the parcels post opens up a ready means of communication direct with the manufacturing chemist.

A convenient method of preparing the acid solution, and one requiring little or no chemical skill, is to decompose calcium sulphite with sulphuric or oxalic acid, filtering out the insoluble lime salt. If definite proportions of the materials be adhered to, a solution of uniform strength can be prepared at any time at a few moments' notice, provided the calcium sulphite be pure. There, however, is the difficulty, and this plan is only recommended to those who do not care to follow a more difficult one. For a more perfect result proceed as follows:—Fit a glass flask or retort with a good cork, through which a bent glass tube passes; in the flask place some strong sulphuric acid and a few clippings or turnings of copper. Arrange so that the glass tube dips down to the bottom of another vessel containing distilled water, apply heat to the flask, and allow the gas to bubble through the water until it is saturated. If a solution of carbonate of soda be substituted for water, saturated with gas and then mixed with the same quantity of carbonate solution as that used at first, the result will be a solution of the neutral sulphite. The operation must be performed out of doors or under a flue with a good draught, as the fumes given off are very suffocating.

HINTS ON ARTISTIC MOUNTING.

There is no question whatever that, since the introduction of gelatine plates, the art aspects of photography have undergone a marked improvement. Pictures which, comparatively, a few years back were looked upon as really artistic productions would scarcely pass muster at the present time, and it is very gratifying to all that the general public is at last beginning to fully appreciate artistic qualities in photographic pictures.

Now, seeing that the artistic merits of the pictures themselves show so great an advance, and that these qualities are being appreciated, it becomes important, as we mentioned a fortnight ago, to devote more attention than hitherto to the subject of the mounting and framing, so as to render the picture an artistic one in all its bearings. With this end in view we shall now redeem the promise made at the time, and here give some practical details of mounting on what is technically known as "linen and stretcher." This system of mounting for large photographs, whether portrait or landscape, when neatly done is far more artistic than that of placing the picture in the orthodox cut-out mount, and, at the same time, it possesses the merit of novelty.

The first thing, in commencing operations, is to decide how much margin is desirable to the picture, and then to get a light frame or stretcher of the proper size made in pine, about three inches wide, morticed and glued at the corners. It is best to have the inner edge of the front of the frame rounded off, so that there be no sharp edge that can mark the margin of the picture when finished. Any carpenter will construct this for a trifling sum, and many picture-frame makers and artists' colourmen keep suitable stretchers in stock of different sizes. It is not necessary or desirable that the frame be "keyed" at the corners, similar to the stretchers of canvases for oil paintings; neither need it be so strongly made. However, it should be constructed of pine wood, as that is less liable to warp or cast than common deal.

On this frame must now be strained a piece of thin calico of fairly-good quality, and secured on the edges with small tacks. The calico need not be strained very tightly, as the after-treatment will tighten it up considerably. We next require some paper with a fine texture and of good colour wherewith to cover the calico. This paper should be sufficiently strong to allow of being conveniently handled while wet without fear of its tearing. That known as "drawing cartridge" is very suitable; but cartoon or continuous drawing-paper is far preferable, in consequence of its fine texture and pure whiteness, which it will retain better than most papers. It may be procured from all artists' colourmen, of various widths—from thirty-six to sixty inches—and of any length up to one hundred yards; so that, as a rule, it will be found not to cut so much to waste as that supplied in sheets. It may also be had of different shades and thicknesses. For our present purpose white will be found the best; for the smaller-sized pictures the thin is to be preferred, and for the larger the thick.

A piece of this paper is now cut sufficiently large to cover the frame and to lap an inch and a-half or two inches over the back. The print must then be carefully trimmed with a sharp knife and straight-edge. In trimming, care must be taken that the print is cut completely through with a single cut; otherwise a sharp, clean edge will not be obtained. It is very essential that it should, as it greatly enhances the effect to the picture when finished. What is now required is a basin of clean water, a couple of clean sponges, and the mountant. The mountant usually employed by picture-frame makers, who generally do this style of mounting, is common flour paste, frequently with alum and size added. But, for photographs, starch paste is far preferable for many reasons. The starch should be made as thick as possible and allowed to cool. When cold it should be so firm that it can be broken between the fingers.

All being ready the cartoon paper is laid upon a sheet—or, if it be very large, on several sheets—of perfectly-clean paper placed on a flat, even board, such as a drawing-board. The trimmed print is also laid, face downwards, on a clean piece of paper. It may be well to explain here that one side of the cartoon paper is much smoother in texture than the other. It is the smoother side that is to receive the print, and, consequently, it is that side which must be placed downwards. One of the sponges is now dipped in the water and the back of the cartoon paper is gone over evenly with it up to the extreme edges, so as to thoroughly moisten it—in fact, to make it decidedly wet. The calico is then evenly wetted with the sponge, and the back of the print also similarly treated. All is now allowed to remain until it is judged that the paper, calico, and print have expanded to their fullest extent. In the case of the cartoon paper this will take a considerable time; hence the reason for wetting it first.

Some of the starch is now put into a clean basin, and, with the dry sponge, is thoroughly broken up, so that it is quite smooth and free from lumpiness. A thin but even coating of the starch is then applied to the still-moist calico and well worked into the fabric with the sponge, taking care that the edges of the frame as well as some of the back are also covered. The back of the cartoon paper is next evenly starched all over. After resting a short time for the starch to penetrate, the stretcher is laid face downwards on to the paper, and the calico well rubbed down upon it from the back. When the calico and paper are in even contact—which is readily secured, as all air-bells are easily forced through the fabric—the frame is turned over, and the edges of the paper lapped over the edges and back of the frame, the corners, of course, being cut out to permit of this being done with neatness. Care must be exercised that the paper is well secured to that portion of the calico which is in front of the woodwork, as this cannot well be rubbed from the back.

Next, the back of the photograph is evenly starched, care being taken that the edges are well covered, but there should be no excess of starch to exude when the print is rubbed down in mounting. While the starch is soaking into the print the cartoon paper should be marked with two or three small dots made with a pencil, to serve as a guide as to where the print is to be placed. All that now remains is to mount the picture just as if it were being done on cardboard, taking care that it is well rubbed down at the edges and, at the same time, that no particles of grit or dirt get imprisoned between the print and mount.

If the print be of a very large size two persons are required in the operation—one to hold it, and the other to arrange it in position and rub it down. The margin of the picture should now be carefully examined; and if it have become accidentally soiled it should be gently cleaned with the sponge and water. But it is better not to wet the face either of the paper or the photograph, if it can possibly be avoided. The picture is now deposited in a place where it can dry free from contact with dust.

While all is wet the picture will look a very unpromising affair indeed; but, as it dries, it will shrink, and eventually become as "tight as a drum." Possibly during the drying the stretcher may twist or cast a little, but this will be of no moment, as it will become perfectly flat when framed. However, the warping may be avoided by securing the stretcher firmly to a wall or other flat surface while it is drying.

On a future occasion we propose to give some practical hints on mounting on india-paper and plate-making.

PATENTS.

A correspondence at present going on in our columns respecting a certain invention for which a patent has been obtained prompts us to offer some remarks upon patents, in what they consist, and the subjects for which they can be obtained.

A patent is virtually a monopoly conferred by the State upon an inventor, for giving up to the public upon certain terms the fruit of his invention. The State in this case is the trustee of the public. In effect it says to the inventor:—"You have an invention of which the public as yet knows nothing, but, as it will be of great utility, and it is undesirable that it be for ever retained as a secret, we will grant you a monopoly in its manufacture and use for a certain number of years, provided you will publish such a clear description of the same as any intelligent man can quite understand." Thereupon the inventor divulges his secret, makes payment of certain fees—at one time so exorbitant as to be deterrent, but now quite moderate—and the State protection is extended to him. This protection implies that the invention is that of the individual making the application, that it is one for a useful purpose, and that it is new in the sense of no prior publication having been made.

Some confusion appears to exist in the minds of many persons as to what forms the distinction between a subject for a registration and one for a patent. Broadly speaking, an ornamental design may be protected by registration; a piece of mechanism is a subject for a patent. The now extinct Ottewill's registered folding camera was, as implied in the name, made the subject of a registration, and, because of ignorance on the part of the public, no attempt at infringement was ever made, as it was believed that the protection of registration was all-sufficient. But had any case ever been brought before the courts it would have inevitably broken down, as it would then have been shown that the protection of registration applied only to such a design as could be drawn upon a flat surface, and not to any piece of mechanism involving configuration of parts. If an ornament, such as a floral or geometric design, had been introduced upon the top or sides of the camera *that* could have been protected by registration; but the camera, as a camera, is a subject for a patent.

A good and valid patent may be obtained for anything formed entirely out of a well-known and even patented parts, provided these parts are combined in such a manner as to form an apparatus not previously in use. But, while the inventor of such combination can obtain a patent for it which shall be valid, he will not be at liberty to make use of it until he has previously made arrangements with the proprietors of the respective parts referred to, provided they have been patented. In the specification of his invention he virtually says:—"I take that wheel which has been previously well known and I combine it with this lever and that pulley, both also well known; and by this combination, not previously known, I produce certain effects. I claim the combination, not the individual parts of which it is composed, as my invention."

A new application of a previously-existing invention is also permissible under certain circumstances. The yellow alloy known as brass is composed of copper and zinc, and in compounding these two metals it would be difficult indeed to specify proportions that have not been employed for some one or other purpose; yet, when Muntz obtained a patent for the application of a particular brass—the proportions of which it was formed having been specified—to the sheathing of wooden ships as a substitute for the copper previously in use for that purpose, an outcry arose, and much litigation ensued. The courts, however, ultimately decided that the Muntz-metal patent was valid. From this we may learn that minute differences in not merely the nature, but in the application, of an invention are recognised in the Vice-Chancellor's court when patent cases become subjects for adjudication.

THE CHOOSING AND USING OF A CAMERA.

A discussion of a very interesting character regarding what has been termed the "camera of the future" is at present proceeding in our columns, and its continuation can be productive of nothing but good, carried on as it is by gentlemen and with courtesy. At its outset the requirements of the tourist, who desires as little baggage as quickly unlimbered as possible, formed the chief topics under consideration; but photography and photographic outfits are too important to be treated from a single standpoint, and the photographer who needs to take out every convenience capable of being a real help to him is by no means a factor in the question that can be ignored. Perhaps he may mainly be found among professional ranks; but, at the same time, he exists and has requirements which may on no account be passed over. His first demand is efficiency, and then convenience, portability, and adaptability. His camera must be steady and, of course, provided with a swing-back. It should be as compact as possible and as easily to be used; in fine, must be a thorough combination of strength, convenience, and lightness.

Though the last two considerations have been well treated, some very important qualifications have been almost ignored; and, seeing that as much as possible is naturally always attempted to be carried out with a single camera, it will not be an inopportune moment to supplement the discussion by some practical remarks with this bearing, which shall also enlarge upon points of prime importance, consistent with the requirement that every class of work should be provided for in the one instrument. Whether such an instrument exists is another question.

We first take under our purview the tailboard. It will be noticed that the presence of a tailboard is almost constantly assumed; yet we venture to state that a camera with a tailboard is an unmitigated nuisance. Many patterns are to be had without such an *addendum*, and the practical photographer is aware of the great difficulties which frequently attend upon its use. There is little inconvenience with small apparatus; but when a 12 × 10 camera is used what can a man do with a dozen inches of tailboard under his chin when taking a dimly-lighted interior, a thickly-wooded glen, or an architectural view? Such subjects often require a lens with a focus of little beyond half the length of the plate, and it is then next to impossible to clearly see the most important part of the picture sufficiently closely to ascertain upon the ground glass the extent of the subject embraced. With a camera, however, which extends from the ground glass frontwards no difficulty whatever is experienced; the darkest view is easily seen, as the head can be placed in any position relative to the ground glass. The ground glass does not, as is so often supposed, exhibit the view as a picture equally brilliant in every direction. To see it clearly when the illumination is dim and the lens has not a large angular aperture it is necessary, as the practical man well knows, to place the eyes almost in a line with the image and the centre of the lens. We would, therefore, emphatically say that when choosing a camera, all other things being equal, the one without a tailboard should be selected; and we may further say that sufficient importance is rarely given to this consideration.

From the back of the camera we pass on to the front. When the tailboard is dispensed with the front of the camera has to be furnished with some analagous provision; and in too many cases this construction introduces another evil, which is not always either taken into account or thought of when purchasing a camera.

We refer to the possibility of the field of view being limited by the bearing upon which the front moves; whence it may happen that a negative when it comes to be developed may have a patch of almost bare glass projecting into the field of view, thus completely spoiling the picture. This is, again, not a light evil; but it is possessed by some very well-known cameras of otherwise most excellent and ingenious construction, both English and American. The camera may be of such a design that it will not show with a long- nor yet with a very short-focus lens. As a matter of fact, we have seen the work of professional photographers quite marred in this manner; yet it would be avoided with no great exercise of ingenuity if only the maker would exercise it or think it called for.

We saw a capital 10 × 8 camera the other day which had a folding framework in the front that was kept folded up for a short-focus lens, and let down for use with those of medium or long focus. With, however, an eight-inch focus lens—a size of wide use for a 10 × 8 plate—we found that the upright plate had a full inch and a-half cut off its usefulness by the image of the front bar of this extension framework being thrown upon the lower part of the plate. This could have been entirely avoided by hinging this front in two pieces. A similar result (the restriction of the field of view) is to be perceived in most patterns where the focussing is performed by the lens, and not the ground glass, being moved too and fro. The full force of this last consideration can only be completely demonstrated when the photographer has an important work in hand, and he finds that his favourite camera —mostly used with a plate placed horizontally—fails him at a critical moment with a subject requiring a short-focus lens worked with a plate vertically placed.

Then, again, upon this very point of upright or vertical position of the plate: all designs for a perfect camera will be incomplete which do not include a reversing back or its equivalent—a reversing back, we may explain to the less-skilled of our readers, being a loose framework to hold the dark slide, and capable of having its position reversed so as to enable the dark slide to be placed in either an upright or a horizontal direction, the power to do which is of great usefulness. Indeed, we may say that we think this comparatively recent invention one of the greatest practical boons given to the profession for a long time past.

The tyro often asks the question as to the difference in the use of a vertical and of a square camera, which, with the dark slides also, he sees the price lists always quote as being different in price. The answer is obvious; but with a reversing back a square camera only could be employed, a counterbalancing advantage, however, being found in the diminished price of the dark slides, which are necessarily constructed narrower in one direction than the other. Then the photographer, upon commencing operations, need be under no anxiety in regard to the position of the plate in the slide, as often happens with a square camera. With a reversing back he can put his plate in either direction, and can always be certain how the plate lies in the slide without any need to fly to the dark-room or to the changing-box.

There are many other considerations that we might dwell upon, but they will serve for another occasion. We have said sufficient today to lead any intending camera purchaser to look upon the instrument under additional mental illumination.

It would appear as if the determination arrived at some time ago to enforce the law in the suppression of the improper use of the royal arms by photographers and others who are not qualified to do so is about to be enforced. We learn that on Tuesday an application for a summons against a well-known firm was made at Marlborough-street Police Court for styling themselves "photographers to the Queen," and for making use of the royal arms in connection with their business. The summons was made returnable on the 30th of this month. This being the first case of the kind that has been brought before a court for adjudication much interest will, doubtless, be felt in the result.

The performance organised by the Balloon Society on Monday last for the purpose of celebrating the "centenary" of ballooning in England came off at Moorfields, the drill ground of the Honourable Artillery Company at Finsbury. Three balloons were sent up—one of them, the "Monarch," carrying our enthusiastic friend, Mr. Cecil V. Shadbolt. Great and special preparations had been made for the supply of the necessary gas to fill the three large balloons, and after their departure the surplus energy was, we believe, let off in the form of speeches.

From an announcement in another column it will be seen that the closing time for the receipt of exhibits intended for the forthcoming Exhibition in Pall Mall is now very near—indeed, will have passed when our next number appears. Lest any of our readers may have forgotten the necessity for action at this time we give them a reminder. From reports that reach us privately we believe that this year's collection will contain more than the average of foreign work; so it behoves our own representatives to do their utmost.

We learn with regret that the American fortnightly journal, *Photography*, which was started only a few months ago, in Chicago, has ceased to exist with the number of the 15th of the present month.

As a matter of journalistic enterprise it is worthy of notice that *Harper's Weekly*—a New York illustrated paper—has, in connection with the recent meeting of the British Association, given a series of portraits of the leading scientific men of Great Britain and the Association. Amongst these we are glad to find that of Mr. James Glaisher, F.R.S., the well-known and popular President of the Parent Society.

Iodised collodion is now nearly a thing of the past, but we have just come across a new application of iodine. Encountering one day a bottle, on the label of which the word "iodised" was very prominent, but the shape of which was not collodion-like, we found it to contain "iodised cod-liver oil!" Our first thought was that "they will 'iodise' anything now that collodion is out of fashion;" but we have since heard a good deal of the beneficial and curative effects of this novel preparation. In one special case that has been brought to our notice the value of the preparation has been shown in an unmistakable manner. Iodine manufacturers may, therefore, note that their occupation is not yet gone.

A long time is required to thoroughly bring the fact home to book illustrators that there is such a mode of illustration as permanent photography, and that an absolute *facsimile* is produced by its means. We still have hand-drawn or written reproductions of maps and similar subjects, and the days of elaborate and expensive prettinesses of engravings from photographs of natural phenomena—indifferent photographs, it may be, but still containing the only evidence available—are not departed. Yet photographic aid is constantly being brought to bear in an increased degree, and every evidence of its value is satisfactory. An excellent case, bearing on the point we persistently maintain, occurs in the current number of the *Athenæum*, which, criticising the illustrations to a work of archæological interest, says:—"The photographic *facsimiles* of the map and bird's-eye view of the castle, drawn by Sir C. Hutton's steward in the year 1588, are far superior in authenticity to the repetitions of those drawings given by Hutchings in his county history." Yet the pretty engravings and the striking effects of the cartographer's art will continue to flourish for a long time.

The straits to which photographers in out-of-the-way places are frequently reduced have often formed the basis of amusing stories; but it is some time since we had so interesting an account of embarassments overcome as that given by a gentleman at a recent meeting of the Virginia State Pharmaceutical Association, who was describing his experiences of the difficulties attending pharmacy during the civil war in America. He said:—

Nitrate of silver was soon in demand. An artist friend in Richmond, and in the employ of the Government, wrote to me that he must have some. Fortunately I had several carboys of different acids, and silver was not very hard to procure; indeed, every article, from a silver button to a solid salver weighing some ten pounds, found its way into the greedy maw of nitric acid. But, again, the appliances of the laboratory were wanting. One single half-gallon evaporating-dish was all I had, and I soon found this article was beyond all price. For many months it was true and loyal, doing double duty as a vessel both for solution and crystallisation. The silver, as picked up wherever I could find it, was very impure. This was first dissolved in equal parts of nitric acid and water; then, with a saturated solution of salt, precipitated as a chloride, then carefully washed until all impurities were gone, reduced by zinc to metallic silver, redissolved, filtered, and crystallised. But the hospital soon demanded lunar caustic. Where were the moulds to come from? I drew a plan, and, after much persuasion, a gunsmith undertook the manufacture of the moulds. But first the brass plates had to be moulded, and the foundryman said he had not time to make the pattern, and, even if he had the pattern, had no brass with which to cast the plates. Fortunately I remembered that an expert in pattern-making was then living in Lynchburgh, and he kindly made the pattern. Then I hunted up some old brass, and, after much delay and begging, the plates were cast. But a new difficulty presented itself: I had nothing in which to fuse the crystals. As stated before, I had but one evaporating dish, and I feared to risk this; so, after writing to every city and town in Virginia, I at last procured a four-ounce porcelain capsule, for which I paid the moderate sum of forty dollars. A pair of pincers made of wood—one blade concave and one convex to fit the curved surface of the capsule—formed the handle, and very soon lunar caustic was produced in sufficient quantity to meet the demand. Bad as were the times, we confederates still tried to keep up appearances. Grey hair had to be turned to black, and our friend, Dr. Hugh Blair, used much of this nitrate of silver in the preparation of his most excellent hair dye.

For some time past the American dealers in such photographic chemicals as collodion, ether, &c., have been mulcted in a two-dollar license; but quite lately this has been pronounced illegal by the higher authorities.

Why Tropical Man is Black is the title of a recent article in *Nature*, the general aim of which may be summed up by saying that the writer looks upon the black of the negro's skin as similar to the backing of a plate to prevent the local action being lost or to increase its accentuation. He concludes his paper by giving an extract from Carpenter's *Physiology*, which he considers to demonstrate, extraordinarily, "the truth of the proposition that skin colour is in direct proportion to light rays;" and by saying: "May it not, therefore, be claimed that there is much foundation for the suggestion that the black skin of the negro is but the smoked glass through which alone his widespread sentient nerve-endings could be enabled to regard the sun?"—that the coloured natives are, in fact, a species of walking photometer.

A propos of the subject of the atomic weights of the elements so often discussed in our columns, we may call attention to the fact that the exact numbers representing these weights as usually given in the text-books are not borne out by experiments, and, in fact, the whole subject of the weights of the elements is not in the most satisfactory state. We have on more than one occasion called attention to points of special interest in Mr. F. Wigglesworth Clarke's important series of calculation of the atomic weights, and we now give a list of the weights of a few important elements as found by the best investigators, and also as corrected by an allowance to be made for errors introduced by weighing the silver when it contained oxygen, most samples of silver having been found by Dumas to be thus adulterated, so to speak. (As we have before stated, the weight of a large number of the elements depends upon that of silver):—

	Uncorrected.	Corrected.
Silver	107·923	107·896
Chlorine	35·451	35·478
Bromine	79·951	79·978
Iodine	126·848	126·875
Potassium	39·109	39·083
Sodium	23·051	23·024
Sulphur	32·058	32·058

Our contemporary, the *English Mechanic*, gives some recipes for colouring brass which seem to bear the impress of real usefulness. A black such as is used for diaphragms may be imparted by dipping in or painting with a mixed solution of chloride of platinum and nitrate of tin. The Japanese use for bronzing a boiling mixture of sulphate of copper, alum, and verdigris. Success in bronzing depends upon the temperature of the solution and the article to be coloured. Steel colour is produced by a boiling solution of chloride of arsenic, while a concentrated solution of sulphide of sodium gives a blue colour. A brown colour is developed by keeping the object in moistened sand for some time; another shade of brown by immersion in a solution of nitrate or chloride of iron; and an olive-green by a mixed solution of chloride of arsenic and iron.

ON TOURISTS' CAMERAS, &c.

Having read with considerable interest the various articles which have recently appeared in the Journal on the subject of tourists' cameras and their shortcomings, it has appeared to me that, assuming Mr. A. Pringle to have expressed his wants as an accomplished amateur, and Mr. George Smith his experiences as a practical manufacturer, &c., neither of them have written from the point of view of the principal person concerned—that is, the average gentleman amateur who practises photography as a hobby (among perhaps many others), or who simply wishes, with as little trouble as possible, to secure mementoes of his wanderings.

With the view of ventilating this last gentleman's wants and opinions the following notes are added to the discussion. Do not let anyone imagine for a moment that I wish to pose as an average amateur; but, having launched a small army of them on their troubles during the past season or two, I may perhaps be permitted to know a little about their wishes on the subject. "It is a great bother carrying the apparatus," says one. "It is *too much* trouble ditto ditto," says another. "I *dread* the *impedimenta* necessary," says a third. In these or similar words I venture to say the great majority of tourists would express their principal objection to the kits they employ.

On analysing this objection to carrying the necessary apparatus it is found to be produced by two causes—first, its weight; second, the awkward way it is usually arranged for carrying. These two causes, which at first sight appear distinct, are, as a matter of fact, inseparable; for the weight which a man can carry with comfort depends almost entirely upon its disposal about his person. For instance: a set of apparatus weighing (say) seven pounds can, if supported *comfortably* on the back, be carried during a twenty-mile walk without one's hardly being aware of its presence; while the same set carried in one hand would be to most people an intolerable nuisance.

It is, of course, obvious that any improvement which reduces the weight of apparatus must prove invaluable, since it will enable the tourist to satisfy his longing for larger pictures; but, unless it be a change in the material with which apparatus is made, or Mr. L. Warnerke's roller slide becomes practicable with gelatine films, it does not appear possible that the weight of apparatus as constructed by our first-class makers can, consistent with retaining sufficient strength, be materially reduced.

Coming, now, to the second cause—the awkward way apparatus is usually arranged to be carried: it appears to me there is room for considerable improvement. A thick leather case with sling strap often strong enough to carry twenty times the weight, and together in the smaller sizes weighing as much as a third or even more of the total weight of the kit, is the sort of thing usually employed to contain the camera, &c., and which, when slung over the shoulder, jolts and knocks against the back in a most uncomfortable manner, the result being that it is usually taken off and carried by hand. Besides this, there is the stand, or, in other words, another awkward parcel to carry.

Why should not light, flexible cases be constructed for the smaller-sized cameras, sufficiently strong to protect them from injury, and yet which can be carried on the back with comfort? Something after the style of the tourists' knapsack is what I have in my mind; or, if it be said that unless the case be rigid it will not protect the apparatus from injury when consigned to the "tender mercies" of the railway porter or carrier, then I should still prefer the light case, and pack everything for railway travelling, &c., in a portmanteau. To put the required conditions in general terms: *the tourist's want is a kit in which everything (including the stand) can be carried on the shoulders or back in comfort, leaving the hands entirely free;* or if the stand cannot be packed up with the other things it should fold up to use as a walking-stick.

For a recent trip I made attempts to get a set which could be carried in comfort during long walks and climbing expeditions, and a description of them will perhaps give an idea of what is wanted. "A 5 × 4 patent light camera, please, and let me have *as light a case as possible*, with sling to carry over the shoulders." On receiving the set it weighed, including three backs with plates, three portable lenses and stand, *nearly eight pounds*, the case alone weighing one-third the amount. The first improvement was to get rid of the separate stand. I got Mr. Steward, of the Strand, to make three pieces of light brass tube ten inches long, with U-pieces and clamping screws at one end; also, a light, triangular piece of wood with slots at each angle for the screws to slip in and clamp the pieces of tube tightly to it. When put together the three tubes and piece of wood formed a very short but firm tripod. I likewise obtained at the Crystal Palace three of the so-called "portable walking-sticks," which may be described to those who have not seen them as spiral bands of steel which, when pulled out—the overlapping portions twisted tightly together, and the loose ends slipped into sockets—form perfectly rigid walking-sticks. The loose ends of these tubular sticks, on being placed in the open ends of the short tripod, formed at once a camera stand quite as rigid as an average portable stand, but about half its weight, and which, by being packed in the case with the other things, obviated carrying two parcels.

As regards the practical value of this stand: it has not turned out to be everything one would wish. Several persons on seeing it have suggested that the spiral supports should be made the full length so as to fit at once into sockets on the wood top. This would be a great improvement, but cannot be done unless a different method be employed for tightening them; for, by the present mode of doing so, the arms have to be extended the full length of the spirals. Another fault is that the japan has come off and the iron rusted. To be durable much better material must be employed and by some means prevented from rusting. These modifications effected, a nearly-perfect portable stand for small-sized cameras would result.

Finally: I had a light strap made which fastened the case on the back in the same way as a soldier's knapsack, so that my hands were left free. The total weight now was about six and three-quarter pounds, and the kit could be carried tolerably long distances with a moderate amount of comfort. A much greater improvement resulted, however, by adopting a method of carrying the apparatus employed by a gentleman I had been visiting for carrying his dark slides. The leather case was discarded and the whole apparatus carried in a schoolboy's common flax satchel, whereby the weight was at once reduced to four pounds, and a degree of comfort hitherto unknown to myself obtained.

The next want to portability in tourists' apparatus to which I attach the greatest importance is getting rid of the focussing-cloth. I have heard many amateurs, especially lady amateurs, object very strongly to this at present necessary adjunct. Many will doubtless say this is a purely imaginary objection; nevertheless it is a very general one. In my own practice a thin Macintosh cloth, white on the outside, is always recommended, and it is astonishing what a difference even this little modification makes in people's feelings. As for the thick velvet cloths with their gaudy yellow linings, which dealers usually supply, a single look at them is sufficient to horrify people with æsthetic proclivities. The only way which suggests itself of getting rid of this nuisance would be to hinge a reflector on to the bottom of the focussing-glass, and fill up the sides and top—excepting two apertures on the top for viewing the image—with flexible cloth. If feasible, the additional advantage would be gained in the image not being inverted.

A third improvement wanted is that the lens should not have to be taken off the camera every time it is used; and how is it, by-the-bye, that opticians still recommend the rapid symmetrical as the best type of lens for general work? In these days of rapid plates the exposures required for most outdoor subjects are unnecessarily and too quick to be accurately timed by ordinary cap exposing, besides the convenience of rotating stops. I think eleven out of twelve photographers would recommend the portable symmetrical type of lens as the best to use where only one is employed. Mr. George Smith says he always employs a rapid symmetrical lens having a small stop where possible. Knowing his great experience with lenses I should like him to tell us why he prefers it to a portable symmetrical.

Returning to the subject of keeping the lens on the camera: an arrangement for fixing it so as to be flush with the camera front, with space for removing the cap and rotating the stops, would be very convenient, especially to the great number of amateurs who always use the same lens. Three stops, instead of half-a-dozen, would also, I think, be less confusing in the average amateur's eyes. I can heartily endorse all that has been said regarding the tripod-screw nuisance. Mr. Hare's method of fixing the screw to the top of the stand, as mentioned by Mr. Pringle, is a great improvement.

E. H. Farmer.

GRANULARITY WHEN COPYING.

The articles on avoiding granularity in copying paper photographs possessed great interest for me, as much of my business lies in that direction.

In giving my experience in this class of work I do so with the sole intention of showing by what entirely opposite means similar effects can be obtained, and how that in this department of photographic practice "one man's food may be another man's poison."

The recommendation given in the articles referred to are to illuminate the photograph by a *side* light in order to get rid of the grain. My own experience does not favour this method, as I have invariably found that, from a mountain downward to the minute granulation on the surface of a sheet of paper, the best and, indeed, the recognised way to render a protuberance visible is by the aid of a side light, which, in my experience, applies equally to the nose on one's face as to mountains or granulations on paper.

The principle of lighting a photograph so as to obliterate any asperities of surface is by a process of counterbalancing. If a protuberance or a pit on the surface of paper be lighted from the side it is brought into visibility by the shadow cast from it—a principle well recognised by microscopists in examining minute objects, and by astronomers when viewing the mountains, caves, and general rugosities of the earth's satellite. Whatever may be the experience of others, I find the same principle to prevail in my photograpic copying practice.

I well remember how, several years ago, either the late Mr. Jabez Hughes or Mr. John Werge brought before the public an arrangement for copying paper prints so as not to show their grain, and which, in my estimation, was absolutely sound in principle. It consisted in placing the picture to be copied at one end of a large tunnel covered with translucent paper, the camera being placed at the other end. This ensured a nearly equal illumination from all sides alike; and it comes up to what I have since found, by an extended experience, to be the best conditions for destroying granularity.

In ordinary practice I illuminate the picture by nearly direct light, shutting out all strong side light. To get a beam of direct or front light to fall upon the print I have a mirror placed close to that side of the camera on which the sun's rays are received, and projected directly on to the print. In this way I get rid of granularity or texture; but I invariably find that when I employ a side light the texture is visible.

Again, and as an illustration of another point in which doctors differ: I take special care not to move either the lens or the back of the camera during an exposure. Such movement may, and doubtless will, produce softness to any extent, by placing the image out of focus; but in my own practice I aim at the greatest degree of sharpness attainable, and, therefore, adopt every precaution against movement of the camera.

George Newton.

THE SODA DEVELOPER.

As I have been working in a not too roomy tent in the hot weather of this summer I experienced no little inconvenience from the fumes of ammonia, so I decided to give a trial to some other alkali. I tried first of all potash, but soon gave that up, owing to the "bottle-stout" character the developer acquired, and because of the unpleasant colour of the resulting negatives. I then tried soda, and of this I cannot speak too highly. I would not willingly return to ammonia. I do not mean to say that soda has no disadvantages, for it undoubtedly has; but its advantages very greatly outweigh them.

In the first place, it is much slower in its action, though I do not think it slows the plate; in fact, the result seems to be the reverse. I purposely under-exposed two plates, developing one with ammonia and the other with soda, and the latter was by far the better negative and a quicker printer; but it takes from eight to ten minutes to get sufficient density. Personally I do not mind this, as even with ammonia I like a slow developer. This, however, may be a serious inconvenience to a professional photographer in a studio.

The advantages of the soda developer are its extreme cleanliness and brilliancy of the negatives without hardness, even in under-exposed plates. I exposed a plate at a group which turned out to be under-exposed, and I am perfectly certain that with ammonia I should have got an unprintable negative. I enclose an under-printed proof and also one of a landscape. I gave this four seconds in order to get detail in the near trees, and I think you will agree with me that there is a fair amount of detail in them, considering how much there is in the distance.

Some of your correspondents have complained of frilling. I have never had a sign of it, and have been using four makers' plates. I use the chrome alum of citric acid before fixing (as recommended in the Journal some six weeks ago), but no alum afterwards.

The constancy of the developer is a great charm. An amateur who makes up a developer with ammonia, using (say) half, and has no occasion to use it again for some time, and then only at intervals, really knows little of its strength.

I have not succeeded in doing away with the bromide, as some of your correspondents recommended; for I could get no density except with an excessive amount of pyro.—five or six grains to the ounce. I use anhydrous carbonate of soda, as I then know where I am, and it is much more soluble than washing soda. I employ the sulpho-pyrogallol of the Platinotype Company or a similar compound, and make up the soda thus:—

Anhydrous carbonate of soda	6 drachms.
Sulphite of soda	3 „
Ammonium bromide	1 drachm.
Water	9 ounces.

To develope a whole plate take—

Sulpho-pyro.	60 minims.
Soda solution	1 to 1½ ounce.
Water	3 ounces.

I add the soda by degrees in the ordinary way. The development is under far more control in my hands than the ammonia was. I also have handy ten-per-cent. solutions of soda and bromide, but very seldom have to use them. I find it almost impossible to get a hard negative or to fog one.

On reading over the foregoing I find I have only mentioned one disadvantage of the soda, viz., its slowness. I was going to add the difficulty of getting density, but this is entirely obviated by the use of a bromide. W. N.

P.S.—The negative becomes a cold grey with not a trace of yellow.—W. N.

THE LATE DR. J. J. WOODWARD.

The death is announced of J. J. Woodward, surgeon, United States Army, the well-known microscopist, whose admirable photomicrographs, produced during his official connection with the Army Medical Museum, Washington, have given the pre-eminence to America for this branch of scientific microscopy. About 1866 he undertook an exhaustive examination of the microscopic test-plate of nineteen bands of lines ruled by the late F. A. Nobert, of Prussia, and succeeded in photographing and counting the lines as far as the fifteenth band (at the rate of 90,090 lines to the English inch) by means of Powell and Lealand's dry 1-16th object-glass. Later, using the then new immersion 1-16th object-glass of the same opticians, he photographed and counted the lines in the four highest bands of the same test-plate (19th band ruled at the rate of 112,612 lines to the English inch). These photographs were submitted to M. Nobert, who had up to that period doubted the possibility of resolving the lines ruled in the four highest bands. After inspecting them M. Nobert acknowledged that the lines were resolved and accurately counted, agreeing with his record of the numbers actually ruled.

Dr. Woodward subsequently made a large series of photomicrographs of test-objects, blood corpuscles of man and various animals (on a micrometer plate, so that the respective diameters could be estimated by inspection), and many physiological preparations representing his official work at the Museum, and these formed a notable feature at the Philadelphia Exhibition of 1876. His latest work in microscopy was the production of a number of photomicrographs of the diatom *Amphipleura pellucida*, with object-glasses on the homogeneous immersion formula. The various series of photomicrographs were forwarded from time to time to the Royal Microscopical Society of London, of which Dr. Woodward was elected an honorary fellow in 1875. In the production of his photomicrographs Dr. Woodward used sunlight (with mechanical heliostat), oxyhydrogen light, and magnesium, publishing full details of the methods he practised.—*The Times.*

PHOTOGRAPHY IN BELGIUM.

[From Our Special Correspondent.]

The Production of Belgian Ordnance Maps by Photographic Aids.

In continuation of the description commenced in my last communication of the method of obtaining a design upon copper by photographic aids, for the purpose of reproducing Belgian military maps at *L'Institut Cartographique Militaire*, near Brussels, it was stated that the apparatus for taking reduced negatives from large tracings of the maps is placed in two huts on the top of a hill. The camera is in one hut, and the tracing is mounted on apparatus beneath the slanting roof of the other hut, but so well forward that the direct light from the sky falls freely upon it. The camera will draw out to the length of two metres, and is large enough to take plates 50 × 60 centimetres in size; it is very solidly mounted on a heavy iron stand. The camera is chiefly formed of three wrought-iron pieces of framework—two of them of about the dimensions of the dark slides, whilst the third is but large enough to carry the flange of the lens. This small frame and one of the larger ones are united by means of a copper cone, which thus forms the front part of the camera. The movable back of the camera is joined to the front cone by a bellows body, and its distance from it is regulated by means of an endless screw. The camera rests upon two rails made in the same piece with a circular plate, which turns by friction upon a second disc on which it rests. These two plates have a common axis, round which one turns by the motion of a screw with a handle. The lower plate carries two trunnions, by the operation of which it rests upon a structure of cast iron. A graduated circle fixed under this plate, normal to the trunnions, permits the communication of a vertical angular movement to the camera by means of a winch. By combining this motion with the angular horizontal motion obtained by means of the plates, it is easy to place the optical axis of the lens with scientific precision perpendicular to the plane of the map to be copied. The map is then necessarily truly parallel to the ground-glass focussing-screen of the camera.

The screen to carry the map to be reduced is so made as to carry the map in a truly vertical position. It is so constructed that by means of winches a series of movements can be given in any direction. Two cast-iron uprights, which serve as guide rails, carry a platform, to which a vertical motion can thus be given. This platform carries another, to which a horizontal movement can be given by mechanism constructed on the same principle. This second support carries apparatus by which a swing motion can be given to the map, and it has four fastenings to hold the plate carrying the design.

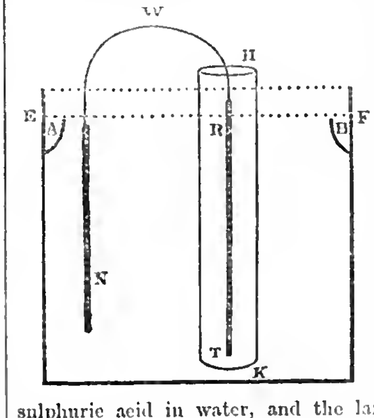
The camera with its stand runs upon rails truly levelled, and laid in a direction perpendicular to the face of the screen. Thus the adjustments of the whole apparatus to reduce the map with exactitude are firm, heavy, and work with scientific precision.

For the very large plates used in this apparatus the wet collodion process is found, all things considered, to be the best. Gelatino-bromide plates have, however, sometimes been tried, and in the days of old even the Taupenôt process and Russell's tannin process have been used. Rapidity is no object; the chief points desired are clear whites and blacks and good definition. Collodion, with a somewhat acid reaction on the bath gives this, and the intensity is obtained by the excellent plan of using bromide of copper, as described in my last.

The map has now to be copied from the negative upon thin sheet copper. A proof is first printed upon carbon paper, and the undeveloped sheet is placed face downwards upon the copper. Four thicknesses of dry blotting-paper are then laid upon the back of the paper proof, and upon these four wet sheets of bibulous paper: then without a moment's delay the whole is subjected to the hydraulic pressure of 200 atmospheres. By this clever plan the proof is under immense pressure before the moisture has time to first work its way through dry sheets, so that when the gelatinised carbon paper is at last wetted it cannot expand under the pressure; if it did so the ordnance maps would not be true to scale. Neither the paper nor the gelatine is allowed time to swell before the pressure is upon it, and the pressure is continued for half-an-hour.

The map is then developed upon the copper by means of warm water. The plate is next allowed to dry, after which plumbago, of specially-selected good electrical conducting power is distributed over the plate with a large, soft brush. The plate is breathed upon at times to facilitate this blackleading operation, which enables the copper, subsequently deposited by electricity, to spread over the ridges of oxidised gelatine as well as over the original copper plate. Without the film covering of plumbago the gelatine lines forming the design would have no appreciable conducting power for electricity.

The accompanying diagram represents the means by which the electrocoppering is performed. It will be seen to be of the simplest and cheapest description, no separate battery being employed. The battery and decomposition cell are in one. In the arrangement at the Brussels Military School the porous cell H K is seventy-five centimetres high and twenty centimetres in diameter. The zinc plate R T is seventy centimetres long, eighteen centimetres wide, and one centimetre thick, connected with the copper plate N, with its map design, by the wire W. The blackleaded face of N is turned towards the zinc plate R T, and is twenty centimetres from the exterior of the porous cell. The porous cell is filled to the level E F with a ten-per-cent. solution of sulphuric acid in water, and the large outer vessel is filled to the same level with a saturated solution of sulphate of copper. The electro-deposition of the copper then goes on slowly, it taking from ten to thirty days to throw down a plate of sufficient thick-



ness. As the copper is slowly deposited upon N, the sulphuric acid of the salt is deposited upon the zinc plate, which it slowly dissolves. The sulphate of zinc formed in excess crystallises on the outside of the porous cell. In course of time some free sulphuric acid finds its way through the porous cell into the sulphate of copper solution. As this interferes with the quantity and quality of the copper deposited Lieut. Massaux neutralises it with oxide of copper. It is not necessary to perform this neutralisation more than about once in six months. Acidulated water has to be added to the zinc cell now and then. In order to keep up the saturation of the sulphate of copper solution, crystals of sulphate of copper are placed in vessels pierced with holes, and suspended at the four corners of the outer tank; one of these vessels is represented at A and another at B. When, as is usually the case, the copper sheet to be deposited is very large, two zinc plates in porous cells are connected with it instead of one. In order to obtain the electro-deposition of good malleable copper, it is necessary that the surface of zinc employed should bear a certain relation to the area of the surface of the copper, and the distance between the zinc and the copper plates is a matter for regulation. Unless the intensity and quantity of the current be properly regulated it is possible to throw down the copper either in a brittle, crystalline condition, or as a soft, brownish-black mud. The rule given by Alfred Smee for obtaining copper in the malleable condition is that the current shall be so strong that free hydrogen is almost on the point of being given off from the copper plate, though it must not be strong enough for the actual evolution of hydrogen. The copperplate designs obtained by this process are very fine, and will bear high magnifying power.

M. A. de Blochouse uses the hydraulic press method of placing designs upon zinc, and at the Brussels Military School, as we have seen, it is used to place designs upon copper. It is preferred to the plan of printing direct from the negatives upon the plates themselves. The method employed at the Military School to impress designs on stone and on zinc is the following:—A ten-per-cent. solution of bichromate of potash is mixed with an equal bulk of a twelve-per-cent. solution of gelatine. The resulting mixture, therefore, contains—

Bichromate of potash	5 grammes.
Gelatine	6 ,,
Distilled water	100 cubic centimetres.

The gelatine is of good quality, and the bichromate of potash is purified by several successive crystallisations. This mixture is applied uniformly by means of a soft sponge to the surface of the stone or zinc, as the case may be. In a few moments it is dry, and the surface may be exposed to light under a negative. It is necessary that the surface should be absolutely flat, so as to be in good contact with the negative at every part; the stones, consequently, are very carefully dressed and polished. The duration of the exposure to light is necessarily variable; sometimes about a quarter of an hour to direct sunlight is given, but a longer exposure in the shade is preferred. The stone is then taken into the developing room, the negative is taken off it, and the stone surface is rolled with a mixture of equal parts of ordinary lithographic ink and an oily "transfer" ink. The face of the stone is then gently wiped with a sponge dipped in tepid water containing a little starch. It may be remarked here that this plan of mixing a little starch with the developing water when soft rubbing by a sponge, or otherwise, has to be applied is much in vogue at Brussels; it reduces the friction and the danger of rubbing away any fine details of the original design. Under the action of the warm, starchy water the soluble portions of the gelatine couch come away, leaving the design clear and sharp upon the stone. This design is then inked afresh, and copies worked off as by the ordinary lithographic process.

A desire existed in Belgium for a chromolithographic chart of the country, to the scale of $\frac{1}{20000}$, and at the same time an objection existed to throwing new charges on the Treasury; consequently a rapid and economical plan had to be devised. In the first instance much handwork was necessary, and the results were not quite true to scale. In this fashion the environs of Antwerp were printed off in 1864. Just before this time the method employed at the English Ordnance Office at Southampton had attracted attention, as published in 1862 by the authority of the Secretary to the War Office. The plan, with some modifications, was tried at Brussels, but the results were found to be inexact in the matter of scale—a defect which threw discredit upon the whole system. The difficulty was overcome by using the photolithographic process just described. Major Hannot (from whose reports, as well as from the information and ocular demonstration given me by Lieut. Massaux, I have drawn largely) said that experience had proved that a second-rate design, if on a large scale, and vigorously drawn with a very black ink, would furnish excellent results when reduced by photography, and the work could be done by the less expert draughtsmen. Had this not been the case the expense of the work would have been much more heavy. In printing the maps in colours it is necessary to take each colour from a separate stone, on which the design for that colour has been placed by photolithography. Six stones are necessary for one map. On one of these stones red patches denote houses, lanes, and macadamised roads; on a second water, rivers, and streamlets are inked in blue. Another colour is a ground tint indicating cultivated soil (this indication having been found to be useless is omitted in the later maps); another tint represents gardens, another moors, and another woods and forests.

As attention has been directed in England to the delay in finishing the home Ordnance Survey, those who wish to investigate the matter might compare the speed of work and accuracy of result with what has been done in this respect in Belgium. In the latter country the entire land has been mapped to two or three different scales, and a chart of the nation in six colours printed off by chromolithography.

A PHOTOGRAPHIC WALKING TOUR IN WALES.

[A communication to the Derby Photographic Society.]

Having been requested to write a paper for this Society, and only having a short time for this purpose, I have decided to write on the subject of my holiday. It may interest at least some of my amateur brethren, and perhaps give them a "wrinkle" for the future when they are meditating on what to do with themselves during their holidays. Last Easter a friend and I were talking over our coming holidays, so it struck us that nothing would be better than to have a short walking tour in Wales, and the matter was then and there decided. As the time drew near for our holiday I confess to feeling a considerable amount of pleasurable excitement in getting my "traps" ready. I may as well at once describe the photographic kit which I took with me. In the first place, I took a 5 × 4 camera, by Watson and Sons, fitted with three double backs. The lens was of the rectilinear type (of foreign make, I believe), and having a back focus of seven and a-half inches; it is a most excellent lens, although it wants the maker's name. The camera, lens, and back were fitted into a case of American cloth, and the legs were of a light, folding pattern. The camera, legs, &c., weighed about eight pounds. For changing plates I took with me a folding lantern, which I obtained from Mr. J. Werge, of Berners-street, London. I consider the lantern is so excellent both for changing plates and developing by, and so very portable, that I have brought it for the inspection of the Society. Besides the plates which I took with me I took a few empty boxes and paper in which to pack my exposed plates. Here let me give a word of advice to those who wish to carry plates safely when travelling, viz., let them pack them in their portmanteaus between articles of clothing. I did this, and, although our luggage frequently had very rough treatment, I had not one plate broken.

At last the eventful day (the 4th of August) arrived, and we started from Derby for Conway. As you all know what the weather was at that time, I need not tell you what our journey was like. We arrived at Conway a little after three o'clock, and after making arrangements for dinner and beds I, the impatient photographer, felt bound to rush off and photograph the well-known castle. I first went inside, as I wished to have a "shot" at the interior of the banquetting hall, or whatever they call it; but unfortunately I found my lens was too long in focus to get what I wanted. After trying every position I reluctantly left the interior to try my luck outside. I took two views of the castle—one from near the entrance, the other from the shore. These two views are shown in the prints (Nos. 1 and 2). The next morning we started off to walk from Conway to Bettws-y-Coed by the right bank of the river Conway. The walk is a very beautiful one, but for the first few miles I did not light upon any subject for my camera. After we had gone about six miles we came upon a man with a cart going to Llanrwst with empty soda-water bottles. This good Samaritan offered us a lift, which we thankfully accepted, as we were nearly melted; and, seated on boxes full of empty soda-water bottles, we made a triumphant entry into Llanrwst. There I had my first "shot" for the day, and secured a good photograph of Llanrwst bridge from the river. This is print No. 3.

Resuming our journey, in about three and a-half miles more we reached the old bridge called Pont-y-pair, at Bettws-y-Coed. I at once attacked the bridge, and then took a "shot" from the bridge looking up the stream—the Llugwy. The results are shown in prints 4 and 5. The next view I took (No. 6) was of the stream in front of the "Royal Oak Inn," while my companion went on to secure rooms and see after the luggage. After luncheon we determined that we would go and see the well-known Miners' Bridge. This bridge I consider a decided fraud. In former days it was a strong ladder reared from one edge of the stream to the top of the bank on the opposite side, and there might have been something curious, if not picturesque, about it; but at the present date it is merely a wooden bridge with a hand-rail at each side, and is neither curious nor picturesque. However, I got two nice views (Nos. 7 and 8) of the stream near the bridge. The next morning we were up early and started for the Fairy Glen. Unfortunately, the light came the wrong way for getting the best photographs of the upper part of the Glen; an afternoon light would have been better. However, I got two pictures of that part (Nos. 9 and 10), which were good, considering that the sunlight was almost coming full into the lens. I got three pictures of the lower part of the Glen (Nos. 11, 12, and 13), for which the light was better. We then returned to our hotel, and on the way back I got a view from a field just below the Waterloo Bridge (No. 14). When we got back to our hotel I made inquiries as to a cellar in which I could change my plates. They took me to the so-called cellar;

but, when I got there, I found that it was not underground, and that floods of white light kept streaming in from different parts. This looked bad. However, my friend and I took off our coats, and, after a great deal of trouble, we managed therewith to block out the greater part of the light, and then proceeded to change our plates in fear and trembling. If any plates ran a chance of being fogged mine certainly did on that occasion. However, "all's well that ends well," and the negatives developed as brilliantly as one could desire. After lunch we started for Pandy Mill. I took duplicate photographs of the mill, and show a print from one of the negatives (No. 15); and I then took a picture (No. 16) of the bridge below the mill, which would have been improved if the sun would have kindly got under a cloud for a few seconds. We then went on to the Conway Falls, of which I also took duplicate negatives; both negatives were fair, and I show a print from one of them (No. 17). On our way back to the hotel we came across a lovely pool where we could get a plunge into fifteen or twenty feet of water. We made a mental note of this place. Next morning we were up early, and started off for our pool; there we had a luxurious bathe before anyone was about. You may fancy the luxury of such a bath during the tropical weather we were having. After breakfast we started by coach, intending to drive to Pen-y-gwryd, but at Capel Curig we were so charmed with the scenery that we determined to leave the coach and photograph. Here I got two photographs (Nos. 18 and 19)—one of the stream with rustic bridge, and the other of the stream and trees, with Moel Siabod in the distance. After this we began the hottest walk we had during the whole of our tour. During the entire of our walk from Capel Curig to Pen-y-gwryd there was not an atom of shade, and the heat was intense. How grateful was the shandy-gaff when we reached our hotel. I took one photograph only (No. 20) on this part of our walk.

I had wished to get a good view of Snowdon from this part of the road, but there was a great heat haze over the mountain, which foiled my intentions. After luncheon we started down the Pass of Llanberis, and here I took three photographs, two of which I show (Nos. 21 and 22). The third, which was very good, I unfortunately managed to scratch after it was finished, and it is utterly spoilt. After spending that night at Pen-y-gwryd, we started off on our way to Beddgelert, through the lovely vale of Gwynant, past the Lakes of Gwynant and Dinas; this I consider to be the lovliest part of our whole tour. I show three views of the Lake of Gwynant (Nos. 23, 24, and 25), and one of Lake Dinas (No. 26). When close to Beddgelert I had another "shot." I hardly know what to name the view, so I have called it a view near Beddgelert (No 27). We put up at the well-known "Goat Hotel." After a short rest we explored Beddgelert and its surroundings; but I did not take any more photographs, as I did not care again to risk changing my plates in the daytime. The next day we started off to walk over the mountains to Tan-y-Bwlch. I had two shots at the Pass of Aberglaslyn before we struck off into the mountain path. I show one of these views (No. 28); the other was much over-exposed.

The walk over the mountains is exceedingly beautiful, and I cannot speak too highly of the charms of a certain mountain stream which we came across. There was a lovely deep pool under a bridge, and I should think we amused ourselves for over an hour bathing in this said pool. I show one photograph taken on this walk (No. 29) secured from a place called Croesor. At the end of this walk we came to the "Oakley Arms" at Tan-y-Bwlch, which is a quaint old inn and well worth a visit.

Next day was Sunday, and intensely hot, so the only exercise we took in the daytime was to stroll about the beautiful grounds of the Oakley family. In the evening we took the mail car to Festiniog, and thence went by rail to Dolwyddelan. From this place we walked by Pont-y-Pant to Bettws-y-Coed, and I only regretted that it was late in the evening, for the scenery was beautiful. The next morning, after a bathe in our favourite pool, we set off for the Swallow Falls; but, alas! on our arrival there, just as I was setting up the camera, down I fell with it on to the rocks. The camera was an utter wreck, and one of my legs was damaged. However, I cared more for the camera than I did about my leg, for I was just about to attempt some lovely pictures.

This ended our tour, and we came back. In conclusion: I may say that my exposures ranged between one second and two minutes, and that the quantity of soda and milk which we swallowed would have floated a good-sized fishing smack. CHARLES E. ABNEY, B.A.

WHERE TO GO WITH THE CAMERA.

[It is hoped that this series of articles will be continued at regular and frequent intervals during the vacation months, and we shall be glad to receive contributions to the series from any friends able to treat of new and interesting ground.]

BOURNEMOUTH AND ITS NEIGHBOURHOOD.*

THE Madeira Walk for invalids is in the gardens that run right through Bournemouth and continue on for over two miles. The "walk" forms at almost any point a pleasing picture; but with trees sunshine is needed, and a negative taken either before the sun is too high, or towards the afternoon with the long east shadows, gives the best result. Expose for the shadows and let the lights take care of themselves, using but little pyro. at the beginning. One of the most successful examples of this arrangement of light is a picture of Branksome Chine, Bournemouth, taken by Messrs. Debenham and Gould, photographers, Bournemouth. The sun is evidently well to the front, left of the camera, and just shines on the sides of the trees—one side being in high light and the reverse in deepest shadow, giving a Payne-Jennings effect; in fact, the whole series come nearer his work than any photograph I have ever seen. Bournemouth has been favourably gifted with regard to good landscape views. Messrs. Vaughan and Whitfield exhibit some large examples, chiefly in carbon—notably, *Shoeing the Mare;* and Messrs. Day and Son's landscapes are like real gems—not large, but exquisite little "bits."

Close by the Madeira Walk is St. Peter's Church—a most beautiful structure. The spire of this church shows to advantage all over the town, and often makes a pleasing addition to an otherwise uninteresting composition. The edifice is in Mr. Street's most happy style, and the interior—architecturally elegant and captivating—is well worth a couple of plates, for which permission must be obtained; for, although the church is always open and is perfectly free so far as pew rents are concerned, I was given to understand that certain amateurs had abused the privilege accorded to them, and the vicar is very particular now as to whom he accords permission. The churchyard adjoining—a remarkably pretty one, and exceedingly well kept—is universally admired, and contains a large cross over twenty feet high. The general effect is most striking, for besides this cross most of the tombstones are also in the form of a cross. Being of white marble, with red, black, and gold letters, the effect amongst the pines and firs, especially during sunshine, is most charming.

There are other churches and chapels in and around Bournemouth, but the Roman Catholic church is the only other one that I noticed which calls for special attention, and this because its architecture is considered to be as pure and chaste an example of the Gothic style as any building in the South of England.

The various chines and ravines are a curious feature at Bournemouth, and these require a late sun with strong light and long shadows to produce anything like a pictorial effect. The pier should be taken looking east and west, getting in one or more of the seats and sandhills as foreground. Take these views when some of the steamers or yawls are about; otherwise the sea looks flat.

From the pier steamers frequently start for Portsmouth and Southampton; also for the Isle of Wight, calling at Yarmouth, Totland Bay, Alum Bay, Cones, and Ryde. Excursions are also made round the Isle of Wight, passing the Needles. Now, on board the boat the captain is supreme. Everyone is bound by his orders, from which no appeal is allowed; therefore, if you intend taking photographs on board by all means obtain his permission first, or otherwise you may be told to take away that "darned machine!" A rapid shutter enables passing ships to be secured, *if the weather be calm;* for under other circumstances we find only the hull or a fine set of furled sails and no ship. Then there are excursions to Branksea or Brownsea Island, for it is known by either name. This is the outing *par excellence.* The island belongs to the Right Hon. G. A. F. Cavendish Bentinck, M.P., at the present time, and, unless an excursion visit is made by the "Lord Elgin" steamboat, permission to land must be obtained. "My island," said a newspaper with the "largest circulation in the world;" and at one time a part proprietor of the *Daily Telegraph* was the owner of it. There are plenty of negatives on this island; for there are no police, no poor, no public houses, no rates, no taxes, no gas, no beggars, no business competition, no legislation, no catching of trains, no van-demons, no school board, no burglaries, no squalor, no poverty, no walls or palings to fence off intruders. Old Father Neptune has girt it round with the briny sea, and a notice-board warns the intruder not to land without permission. Having landed from the above steamboat the first thing that attracts attention after the aforesaid notice-board is that the landing place is called Piazza del Castello. Proceeding on, one passes the Cassino, Villino, Magazino, Venetia Park, and then the Castle.

"My island" is at the entrance of Poole harbour, and according to the newspapers of last month things are slightly different at Poole. The castle was in olden time a fortress, and legendary lore says Canute landed there. Now the castle contains all the vast art-treasures its present owner has collected abroad, though he does not reside there but in a comfortable villa close by. I cannot remember half the curios, but there are statues from Rome, Italy, Corinth—of Pan, water nymphs, Flora, Hercules, &c., old Corinthian pillars and capitals, stained and ground glass, old fonts, tablets from ancient continental churches, carvings in wood and stone, fountains, beautiful ferns and exotics, winged lions, oak doors, Roman bath—all these things and many others lie scattered about all over the building, "upstairs and downstairs, and in my lady's chamber." There is no attempt at numbering, no putting in order, and no stiff museum style about the place. Many of the marble statues, fonts, &c., look as if the carriers had just put them down in the first convenient place and left them there.

The church is a gem, and from notes from a little work given us by Mr. R. H. Fry, the managing director of the Branksea Island Company, Limited, who make the Branksea pottery, I find that the oak roof came from the council chamber of Crosby Hall, as did the gold and silver

* Concluded from page 551.

repoussé lamps suspended from the cross beam; the coloured glass from Sainte Chapelle, Paris; the brass candlesticks (1716) from the Benedictine Monastery near Padua; and the winged angels were part of the altar of St. Lucchia, Venice—one of which formed the reading desk and the other the pulpit. The baptistry contains a picture by Murillo. The rood screen comes from one of our city churches, and the screen at the west-end once adorned some Roman place of worship. The chairs and hassocks are all hand-worked. In the churchyard—here so well kept—is a rare specimen of the weeping holly. In the conservatory the well of red marble, with its marble conduit or "lavabo," comes from St. Salvestro, Venice. Mr. Fry was most kind to our party, and presented my wife at parting with a cabinet picture containing his daughter and "Carlo," the watchdog, standing against a magnificent piece of carved marble. There, as at Bournemouth, are pines, the turpentine from which is said to be so soothing for weak lungs. Birds of all sorts—peacocks, pheasants, ducks, wild and tame, pigeons, poultry, &c.—all lend enchantment to this picturesque spot.

Returning by water to Bournemouth the cliffs show some good bold points well worth a plate, as the boats keep pretty close to the shore, and no difficulty is experienced. From Bournemouth visit Christ Church, with its priory. A view across the river can be taken from 10.30 till the afternoon, as it faces south. There is capital fishing in the river. The interior of the priory suffered much from the Commonwealth, and has not been to any extent restored. Here is to be seen a fine monument to the poet Shelley.

As the station is some distance from the town take the hotel 'bus. The same applies to Bournemouth, and with double force if one arrive at the East station—that is, the station from London and the east side of Bournemouth. Swanage, a harbour town like Poole, does not present any special features. Both make pleasant excursions. The Tillywim lighthouse and its ridges of rocks at low water are worth a plate. This also faces the south, but the best view is obtained from the west.

Wimborne and its minster ought not to be missed. The old church is well worth two plates—one close up, just as you come from the market square, and the other from between the church and the station by the brook, taking in the bridge. There are many interesting objects in the church; and the curator—an old man of sixty, who boasts of having been connected with this church, man and boy, all these years—has published a book on Wimborne, price one shilling. To sell one of these books gladdens his heart more than the same sum given as a gratuity. An astronomical clock in the west tower and the ancient books in the library of the minster should also be seen.

From Wimborne we proceeded to Salisbury, but the letter conveying permission to photograph the interior having by some error of the post-office been sent astray, and the weather coming on dull, it was thought desirable to return home.

I believe I have not done justice to the beauties of Bournemouth, and feel sure one might "fire off" over a hundred plates, all of which would probably produce beautiful pictures. There is nothing about the place of an ancient character, as will be gathered by the fact that when George III. visited Weymouth there were but three smugglers' huts on the spot now known as Bournemouth.

Respecting the development and changing of plates: the first operation was deferred till our arrival at home, the plates having been tested before starting. The camera was a half-plate one, and had six double dark slides. I found, as a general rule, that if you called upon one of the photographers they would allow you to change the plates; although most of them did not care to permit you to develope them, for the operation entailed trouble. But when you go either early or late—not in the busy part of the day—a man who takes portraits only is much more likely to oblige than the photographer who "goes in" for landscape work.

ARCHER CLARKE.

IMPROVEMENTS IN THE PREPARATION OF PHOTOGRAPHS AND THE TREATMENT OF DRAWINGS OR DESIGNS PRINTED UPON PAPER OR OTHER SUITABLE MATERIAL FOR THE PURPOSE OF IMITATING STAINED, GROUND, CUT, OR EMBOSSED GLASS, OR TO BE EMPLOYED FOR OTHER USEFUL OR ORNAMENTAL PURPOSES.

SPECIFICATION. By GEORGE RYDILL.

MY invention consists in producing, treating, and applying photographs, printed drawings, or designs either upon sensitised, white, tinted, or coloured paper, satin, cotton, linen, parchment, glass, wood, or other suitable material printed or produced from glass negatives, wood blocks, stone, metal, glass, engraved or etched metal plates, or by any of the known methods of printing in one or more colours.

In order to describe my invention and its various applications for useful and ornamental purposes I will explain one process for producing printed copies of photographs.
